PUBLISHERS
AMERICAN MEDICAL ASSOCIATION
CHICAGO, ILL

CONTENTS OF VOLUME 19

JULY, 1929. NUMBER 1

Surgical Applications of Therapeutic Venous Obstruction. Barney Brooks, M.D., Nashville, Tenn.....	1
The Structure of Bone, with Particular Reference to Its Fibrillar Nature and the Relation of Function to Internal Architecture. Henry L. Jaffe, M.D., New York	24
Surgery of the Esophagus. James H. Saint, M.D. (Durham), M.R.C.S., L.R.C.P., Rochester, Minn.....	55
A New Abdominal Incision. J. Tate Mason, M.D., Seattle.....	129
Operative Relief from Pain in Lesions of the Mouth, Tongue and Throat. Walter E. Dandy, M.D., Baltimore.....	143
Bronchobiliary Fistula. M. G. Seelig, M.D., and J. J. Singer, M.D., St. Louis.....	149
Endometrioma of the Terminal Ileum, Appendix and Cecum. F. N. G. Starr, C.B.E., M.B., Toronto.....	152
Thirty-Eighth Report of Progress in Orthopedic Surgery. Philip D. Wilson, M.D.; Lloyd T. Brown, M.D.; M. N. Smith-Petersen, M.D.; Ralph Ghormley, M.D.; John Kuhns, M.D., and Edward Cave, M.D., Boston; Murray S. Danforth, M.D., Providence, R. I.; C. Herman Bucholz, M.D., Halle, Germany; George Perkins, London, England, and Arthur Van Dessel, M.D., Louvain, Belgium.....	154

AUGUST, 1929. NUMBER 2

Osteitis Fibrosa and Giant Cell Tumor. Charles F. Geschickter, M.D., and Murray M. Copeland, M.D., with Foreword by Joseph Colt Bloodgood, M.D., Baltimore	169
The Relation of the Adrenal Gland to the Toxemia of Intestinal Obstruction: An Experimental Study. R. A. Cutting, M.D., Ph.D., New Orleans....	272
Acute Complete Obstruction of the Duodenum Following a Gastrojejunostomy: Cure by Degastro-Enterostomy. John E. Summers, M.D., Omaha.....	292
Pericardotomy for Pyopericardium. L. G. Bowers, M.D., Dayton, Ohio....	301
Ganglioneuroma of Mediastinum Requiring Surgical Intervention for Relief of Obstructive Symptoms. T. F. Riggs, M.D., and L. P. Good, M.D., Pierre, S. D.....	309
Variations in the Extrahepatic Biliary Tract. Meredith G. Beaver, M.D., Rochester, Minn.	321
A Review of Urologic Surgery. Albert J. Scholl, M.D., Los Angeles; E. Starr Judd, M.D., Rochester, Minn.; Linwood D. Keyser, M.D., Roanoke, Va.; Gordon S. Foulds, M.D., Toronto, Canada; Jean Verbrugge, M.D., Antwerp, Belgium, and Adolph A. Kutzmann, M.D., Los Angeles	327

CONTENTS OF VOLUME 19

SEPTEMBER, 1929. NUMBER 3

	PAGE
Traumatic Subclavian Arteriovenous Aneurysm: Final Report. Edgar Lorington Gilcreest, M.D., San Francisco.....	375
The Celiac Plexus and Its Branches. F. Kiss, M.D., Budapest, Hungary, and Harry C. Ballou, M.D., St. Louis.....	399
The Branchial Apparatus: Its Embryologic Origin and the Pathologic Changes to Which It Gives Rise, with Presentation of a Familial Group of Fistulas. Olan R. Hyndman, M.D., and George Light, M.D., Iowa City	410
Lymphatic Drainage from the Peritoneal Cavity in the Dog. George M. Higgins, Ph.D., and A. Stephens Graham, M.D., Rochester, Minn.....	453
Old Nodular Goiter Surrounding Trachea, Posterior to the Carotid with the Isthmus Posterior to the Esophagus: Report of a Case with Sudden Death from Acute Abscess. Miles F. Porter, M.D., Fort Wayne, Ind.	466
The Effect of Intrabronchial Injections of Iodized Poppy Seed Oil 40 Per Cent: An Experimental Study on Dogs. Ralph Boerne Bettman, M.D.; John Kelly, M.D., and Nathan Crohn, M.D., Chicago.....	471
Intestinal Obstruction: Experimental Studies on Toxicity, Intra-Intestinal Pressure and Chloride Therapy. Forrester Raine, M.D., and Margaret C. Perry, M.A., Milwaukee.....	478
A Comparative Study of the Bactericidal Values of Twenty-One Commonly Used Antiseptics. Abbott William Allen, M.D., New York.....	512
Surgical Diseases of the Colon: Cooperative Management. Fred W. Rankin, M.D., and J. Arnold Borgen, M.D., Rochester, Minn.....	518
A Review of Abdominal Surgery. Gunther W. Nagel, M.D., San Francisco; E. Starr Judd, M.D., Rochester, Minn.; Bennett R. Parker, M.D., Chicago; Winfred H. Bueermann, M.D., Portland, Ore., and H. Peiper, M.D., Frankfurt Am Main, Germany.....	526

OCTOBER, 1929. NUMBER 4

Air Embolism from the Pulmonary Vein: A Clinical and Experimental Study. C. M. Van Allen, M.D., and L. S. Hrdina, Chicago, and J. Clark, M.D., Iowa City.....	567
Experimental Peptic Ulcer. James C. McCann, M.D., Rochester, Minn.....	600
Loose Cartilage from Intervertebral Disk Simulating Tumor of the Spinal Cord. Walter E. Dandy, M.D., Baltimore.....	660
Renal Counterbalance. James J. Joelson, M.D.; Claude S. Beck, M.D., and Alan R. Moritz, M.D., Cleveland.....	673
The Delbet Apparatus and the End-Results. Edward T. Crossan, M.D., Philadelphia	712
Trauma to Central Nervous System: Its Effects on Cardiac Output and Blood Pressure. An Experimental Study. Alfred Blalock, M.D., and Hubert B. Bradburn, M.D., Nashville, Tenn.....	725
Thrombo-Angiitis Obliterans: General Distribution of the Disease, Maurice E. Barron, M.D., and Harry Linenthal, M.D., Boston.....	735

CONTENTS OF VOLUME IV

NOVEMBER, 1929. NUMBER 5

Correlations of Internal and External Pancreatic Secretion	
I. General Considerations and Review of the Literature. G. de Takats, M.D., Chicago	271
II. The Histologic Changes in the Isolated Tail of the Pancreas. G. de Takats, M.D., Chicago	277
III. The Effect of Ligation of the Tail of the Pancreas on Dog Blood. G. de Takats, M.D., and I. T. Nathanson, D.S., Chicago	287
Experimental Sarcoma of Bone. Charles I. Connor, M.D., San Francisco	294
Pulmonary Atelectasis and Respiratory Failure. Israel Rosenberg, M.D., New York	300
Cavernous Hemangioma of the Scrotum: Report of a Case. Nathan Winkler, M.D., Baltimore	302
Surgical Wounds in Human Beings: A Histologic Study of Healing and Practical Applications; I. Epithelial Healing. Shattuck W. Henshaw, M.D., Rochester, Minn.	315
Primary Carcinoma of the Fallopian Tube: A Series of Fourteen Cases. Lawrence R. Wharton, M.D., Baltimore, and F. H. Krook, M.D., Fort Smith, Ark.	318
Leukoplakia of the Renal Pelvis. Adolph A. Kutzmann, M.D., Los Angeles	371
Oxygen Content of Blood in Patients with Varicose Veins. Alfred Blahosky, M.D., Nashville, Tenn.	388
Carcinoma of the Colon: Intraperitoneal Vaccination by Mixed Vaccine of Colon Bacilli and Streptococci. Fred W. Rankin, M.D., and J. Arnold Bargen, M.D., Rochester, Minn.	391
Acute Obstruction of the Small Intestine Due to a Gallstone: Recovery Following Operation. Golder L. McWhorter, M.D., Ph.D., Chicago	395
A Review of Urologic Surgery (to be Continued). Albert J. Scholl, M.D., Los Angeles; E. Starr Judd, M.D., Rochester, Minn.; Linwood D. Keyser, M.D., Roanoke, Va.; Gordon S. Foulds, M.D., Toronto, Canada; Jean Verbrugge, M.D., Antwerp, Belgium, and Adolph A. Kutzmann, M.D., Los Angeles	322

DECEMBER, 1929. PART I. NUMBER 6

Value of Blood Amylase Estimations in the Diagnosis of Pancreatic Disease: A Clinical Study. Robert Elman, M.D.; Norman Arneson, M.D., and Evarts A. Graham, M.D., St. Louis	943
Fractures of the Transverse Processes of the Lumbar Vertebrae: A Report of Thirty-Three Cases. Paul A. Quaintance, M.D., Los Angeles	968
Gross and Microscopic Structure of the Thyroid Gland in Man. William Francis Rienhoff, Jr., M.D., Baltimore	986
The Gallbladder: Its Functions and Some of Their Disturbances in the Light of Recent Investigations. Béla Halpert, M.D., Chicago	1037

SURGICAL APPLICATIONS OF THERAPEUTIC VENOUS OBSTRUCTION *

BARNEY BROOKS, M.D.

Professor of Surgery, Vanderbilt University

NASHVILLE, TENN.

It is remarkable that a process so apparent as the circulation of the blood could have remained undiscovered through so many centuries during which there was an accumulation of knowledge of other more complex phenomena. If one only contemplates the vast number of opportunities which were presented for the discovery of the circulation of the blood and recalls the simplicity of the experiments of William Harvey, one is amazed that this discovery should have been deferred so long. It would seem as if a sort of mysticism always assigned to the cardiovascular mechanism had prevented an appreciation of its simple realities. Discussions of the problems of the circulation of the extremities still contain many vague ideas and few definite terms. It would seem worth while, therefore, to discuss some therapeutic measure applicable to disease of the circulation of the extremities with the object in view of tracing its historical development and collecting the existent definite knowledge concerning its fundamental principles.

Therapeutic venous obstruction is as old as medical literature. * It is quite natural that intentional obliteration of veins should have been first used in the treatment of conditions in which there were external manifestations of disease in the veins. Hippocrates¹ described a method of obliteration of a varix in which needles were passed into the dilated veins. Paul of Aegina,² Celsus and Galen described methods of excision of varicose veins, and this operation is said to have been mentioned by Pliny and Plutarchus. The fact that the celebrated Caius Marius submitted to an operation for varicose veins without being bound is mentioned as an evidence of his fortitude. In more recent times, Max Schede³ and Trendelenburg⁴ revived the operative treat-

ment for varicose veins. During the past few years, there has been a marked revival of interest in therapeutic venous occlusion by injection. It is interesting to note that this method was extensively used and discarded previous to the development of antiseptic surgery.

The origination of the idea of purposeful occlusion of normal veins as a therapeutic measure in the treatment for arterial disease is usually ascribed to Sir George Makins⁵ who observed, from experiences in the South African War, that there was a smaller incidence of gangrene in those instances of arteriovenous fistula resulting from gunshot wounds which were treated by ligation of both the artery and the vein than in similar wounds treated by ligation of the artery alone. It is interesting to note, however, that this observation of Makins was not recorded until his delivery of the Bradshaw Lecture in 1913, and that at this time he referred only to a study of a series of records of arteriovenous fistula.

In a subsequent address, the Hunterian Oration delivered in February, 1917, Makins⁶ went further in his conclusions as to the application of venous occlusion as a therapeutic measure. In this address he advocated the possible value of ligature of the vein as a therapeutic measure in instances in which there is arterial occlusion but no fistulous opening between the artery and the vein. It is interesting, however, to note that in this address, Makins referred to the observations of von Oppel concerning the beneficial effects of simple ligation of the vein in instances of spontaneous arterial occlusion without arteriovenous fistula.

During the World War, this subject was made the principal point of discussion at a meeting of the French Surgical Society in July, 1917, at which time Professor Tuffier⁷ expressed his views on the subject in the following words:⁸

We all know that the three arterial ligations which most often expose patients to grave dangers of disturbance are (1) those of the femoral trunk, (2) those of the carotid at its bifurcation, and (3) those of the popliteal artery in the lower half of the popliteal space. If I believe everything that I have seen of ligation since the beginning of this war, it is that the occlusion of the popliteal in its lower half causes most disasters; gangrene of the limb is very often a consequence of it.

To lessen the chances of ischaemia or of the gangrene following ligatures in these regions, it has been advised to have recourse more often to lateral sutures in all cases where the nature of the lesions permitted it, and I fully share this opinion. There is a great advantage in having recourse to arterial sutures; they are less difficult to place than one believes.

7. Tuffier: *Bull. et mém. Soc. de chir. de Paris* 43:1469, 1917.

8. Halsted's translation.

There is a practice to which I desire again to direct your attention in this connection; it is ligation of the corresponding healthy vein in all cases of ligation of the great vessels of the root of the limbs. This question, raised long ago, can find in actual occurrences some particularly suggestive statistics. There is first a fact which appears well demonstrated; it is that ligation of the vein and of the artery in the case of wounds of the two vessels does not increase the danger of ischaemia. Moreover, the statistics of the English Army, which Sir George Makins has communicated to us, give in this connection the following ratios. Ligation of the artery alone is followed in a general way by gangrene in 40.2 per cent, whereas simultaneous ligation of the artery and of the vein under the same conditions gives 24.5 per cent; and I speak only of gangrene from ischaemia.

The most marked difference is in connection with the popliteal; ligation of the artery alone in twenty-four cases gave favorable results in 58.33 per cent, and gangrene in 41.66 per cent. Simultaneous ligation of the artery and of the vein has given in twenty-eight cases twenty-two favorable results and only six cases of gangrene.

It is interesting to note that Tuffier referred to simultaneous ligation of the vein as "a subject raised long ago." The danger of ligation of veins in the presence of suppuration was emphasized by Pirogoff. After the development of antiseptic surgery, both experimental and clinical observations were reported which justified the conclusion that ligation of the vein with the artery does not entail a risk of gangrene greater than ligation of the artery alone. I have found no record previous to the beginning of the twentieth century which contained a definite statement indicating that ligation of a vein is a therapeutic measure in the treatment of arterial disease. In a private communication, Makins stated: "At the time of the Boer War (1899-1902), I held the generally accepted view of the necessity of sparing the vein."

In a report of a study of the surgical treatment for aneurysm of the subclavian artery, Halsted⁹ discussed the subject of therapeutic occlusion of healthy veins at some length. In this publication, he called attention to the fact that occlusion of the vein, as a method of prevention of gangrene, had been recommended previous to the time of the publications of Makins. He expressed the belief that the first record of the idea is contained in a report of an operation by von Oppel,¹⁰ published in 1908. It is interesting to note that this publication of von Oppel dealt with an operation on a patient suffering from arteriovenous fistula.

It would seem, therefore, that the fundamental principles involved in therapeutic venous obstruction had been considered the same whether this operation was applied to arteriovenous fistula or to arterial obstruction without arteriovenous communication.

I believe that this opinion is erroneous and that careful study of the conditions present in varicose veins, arteriovenous fistula, and in arterial

⁹ Halsted Johns Hopkins Hosp Rep 21:1, 1921

¹⁰ Von Oppel: Arch f klin Chr 86:31, 1908.

obstruction without fistula will show that the fundamental principles involved in the application of therapeutic venous obstruction to these different conditions are not the same.

In order to make myself clear in the attempt to analyze the different conditions in the circulation of the extremities for which therapeutic venous occlusion is indicated, it will be necessary to review briefly some of the most elemental factors concerned in the circulation of blood.

In the beginning, it is worth while to point out that however complex the function of the circulation of the blood in health or the pathologic changes in blood flow in disease may be, the actual circulation of blood is only a fluid flowing through tubes. The physical and chemical characteristics of the fluid may vary and the mechanism of control of the cross-section area of the tubes may be exceedingly complex, but the fact remains that in the last analysis the circulation of the blood is a simple mechanical phenomenon.

If the circulation of the blood in health or disease is approached from this point of view, it is at once apparent that with the assumption of a constancy of the physical and chemical properties of the blood, there are two important variable factors: (1) the amount of blood which passes through a unit volume of tissue in a given time, the volume flow, and (2) the tension of the blood in the vessels through which it is passing, the intravascular pressure. It might be said that if the peripheral circulation is to be discussed from the point of view of its being a mere mechanical phenomena of a fluid flowing through tubes, volume flow was the single important factor since it is obvious that the amount of fluid which flows through a unit length of a tube is dependent on the cross-section diameter of this tube and the difference in pressures between the inflowing and outflowing points, but certain evidence exists which makes it seem likely that nutrition of the tissues is dependent on the conditions of intravascular pressure independent of volume flow. It is also worth while to emphasize another point, the lack of appreciation of which has often led to error. The volume flow of blood must, of necessity, in all instances be the summation of all the blood flowing through every channel of that particular portion of the body under consideration. For example, the cardiac output or the total amount of blood which is put out by the heart in a unit of time must be the same as that which is flowing through every capillary in the body. It is possible to have great variations in the volume flow of blood through any particular organ without necessarily changing the cardiac output or total volume flow. For example, during the process of digestion, there may be a much larger amount of blood flowing through the intra-abdominal organs and a correspondingly less amount of blood flowing through the peripheral structures. This principle is perhaps best referred to as the distribution of blood flow. The amount of blood flowing

through an extremity may be actually greater than normal, in spite of the fact that a portion of this extremity may be receiving a blood flow below that necessary for normal nutrition. I wish particularly to emphasize this point because of conclusions that are now being drawn from certain experimental work in which it is assumed that evidence of an increased volume flow of blood to a lower extremity is taken to mean that all of the tissues of this extremity are receiving an increased circulation.

The distribution of the blood flow through tissues must be considered as applying to small volumes as well as to relatively large volumes of tissue. It has been clearly demonstrated that blood may be flowing freely through a capillary at a time when no blood is flowing through another capillary a small fraction of a millimeter distant.

FUNDAMENTAL PRINCIPLES OF THERAPEUTIC VENOUS OCCLUSION

After this definition of terms, I shall proceed with a discussion of the fundamental principles involved in the application of therapeutic venous occlusion to those conditions for which it has been used.

Venous obstruction as a therapeutic measure has been applied in three conditions: varicose veins with the attendant ulceration, arteriovenous fistula and simple arterial obstruction which may be either acute complete or progressive partial.

1. In instances of varicose veins associated with poor nutrition of tissues, the condition is probably one in which the poor nutrition of the tissues is the result of an already existent venous obstruction that operates to produce a diminished volume flow of blood through some of the superficial tissues. The only reason for the occlusion of the dilated veins which has ever been assigned, paradoxical as it may seem, is the ultimate removal of this existent venous obstruction. Further discussion of this particular phase of surgery of the venous system is not appropriate at this time.

2. In instances of arteriovenous fistula, the condition is one of an abnormal communication between the artery and vein through which the blood, destined for the tissues supplied by the artery distal to the fistulous opening, is shunted directly into the vein. In this condition, there are two circulations: a normal circulation through the capillary bed of the extremity and an abnormal circulation through the fistulous track. The arteries, capillaries and veins of the extremity are presumably normal. The anatomic defect lies solely in the fistulous communication between the artery and the vein. The physiologic defect lies solely in the diminution of the volume flow through the capillary bed because part of the arterial blood passes directly into the veins through the fistulous opening. From this, it is obvious that any therapeutic

measure must have as its prime object the diversion of the volume flow of blood of the abnormal circulation into the paths of the normal circulation.

3. In instances of simple arterial occlusion without arteriovenous fistula and without any demonstrable disease of the veins, the condition is one of a reduction of inflow of blood into the arterial tree distal to

Fig. 1.—Conditions of the circulation of the extremity in the presence of varicose veins of the leg. The hydrostatic pressure in the absence of valves in the saphenous vein results in an increase in the venous pressure in the superficial veins. There is, therefore, a disproportion between the resistance offered in the capillaries of the superficial circulation and the capillaries of the deeper circulation. In this figure and figures 2, 3, 5, 6, 7, 8 and 9, *V* indicates vein and *A*, artery.

Fig. 2.—Conditions in the circulation of the arm with a fistulous opening between the axillary vein and artery. Blood may pass from the artery to the vein either through the capillaries of the arm or through the arteriovenous fistula. If the artery is obstructed just proximal to the fistulous opening, blood passing through the collateral arterial branch may also pass through the capillaries or the fistulous opening. Obstruction of the artery, therefore, merely results in a diminution in the volume flow through both circulations. The reduction of the volume flow through the capillary bed is probably in all instances proportionately greater than the reduction of the volume flow through the fistulous opening. Simultaneous ligation of the vein at the same level may diminish the volume flow of blood through the fistulous opening and increase the volume flow through the capillary bed. See also figures 4 and 9.

the point of obstruction without a corresponding reduction in the capacity of the outflow channels. There is no communication between the artery and vein other than through the capillary bed, and blood may flow from the artery to the vein through this capillary bed in all portions of the extremity. With an appreciation of the elementary principles of the flow of fluids through tubes, it becomes obvious that

Fig. 3.—Conditions present in the circulation of the arm with simple arterial obstruction without arteriovenous fistula. No communication exists between the artery and vein except through the capillaries of the extremity. Therapeutic occlusion of the axillary vein makes it necessary for the return flow of blood to pass through the collateral vein. A difference of opinion exists as to the effects of the obstruction of the vein on the volume flow of blood through the capillaries. See also figure 7.

such a condition is of necessity associated with a diminution of volume flow through the tissues supplied by the obstructed artery and a diminished intravascular tension in the arteries, capillaries and veins. An artery may be completely obstructed suddenly by wound, ligature or embolus, or arterial obstruction may be the result of a progressive obliterating arterial disease.

It is primarily my purpose in this paper to inquire into the history of the development of the idea of therapeutic venous obstruction for arterial disease, to discuss the fundamental principles involved and to comment on the clinical applications. As has already been stated, the origin of the idea of purposeful obstruction of a healthy vein for its possible beneficial effects in instances of dangerous anemia from arterial occlusion has been attributed to experiences with arteriovenous fistula. The first advancement of this idea is usually attributed to Sir George Makins. I am convinced, however, that the idea had previously occurred to others. From a study of the literature, it seems that Makins did not clearly enunciate this idea until the delivery of his Hunterian Oration before the Royal College of Surgeons of England on Feb. 14, 1917,¹¹ and it is interesting that even at this time Makins included the evidence derived from the operative treatment of arteriovenous fistula as substantiating the conclusion that ligature of a healthy vein is to be recommended in instances of simple arterial obstruction. It is to the credit of Makins, however, that he apparently realized that ligature of the vein in arteriovenous fistula involved somewhat different principles, because he stated in his Hunterian Oration, "Evidence, moreover, exists that under certain conditions ligature of both artery and vein is a preferable procedure. The first example, *not an unmixed or simple one*,¹¹ may be sought in the results observed to follow the application of a single proximal ligature to the artery in cases of arteriovenous aneurysm.

"A more striking example is offered by the ligaturing of the popliteal vein alone for the treatment of senile gangrene of the foot by W. A. Oppel."

It is interesting that Halsted, also, apparently confused the principles underlying occlusion of the vein in the treatment for arteriovenous fistula with the principles underlying the therapeutic occlusion of the vein in instances of arterial obstruction without arteriovenous fistula.

The experience of von Oppel, to which Halsted ascribed the origin of the idea of ligation of the concomitant healthy vein in the presence of arterial obstruction, was briefly as follows:

A man, aged 32, presented the clinical manifestations of a fistula between the axillary artery and vein due to a gunshot wound. Three operations were performed on May 5, 1905. During the course of the operations, frequent observations of the blood pressure were made by Korotkow.

11. Author's italics.

The first operation was completed at 11:30 a. m., and consisted of a double ligation and division of the axillary artery proximal to the aneurysm sac. Following this procedure, the arm became deathly pale and the blood pressure, zero.

The second operation was begun at 3:30 p. m., and finished at 4:30 p. m. The wound was opened. The axillary vein was divided above the aneurysm between ligatures. No change in the arm was noted by Korotkow. The operator then observed that pressure with the finger in the space between the stumps of the divided artery caused the arm to become red and the blood pressure to rise to 40 mm. A search was then made in the vicinity in which the pressure was exerted, and a large vein (v. axilaris profunda) was found. This vein was doubly ligated and divided. The blood pressure in the arm rose to 40 mm. The wound was then closed. When the dressings were applied, it was noted that the arm was getting pale. After the patient was returned to bed, the arm continued to be pale and severe pain developed.

Fig. 4.—The operative procedure of von Oppel to which Halsted ascribed the origin of the idea of therapeutic ligation of the vein for prevention of gangrene. The diagrams are made from von Oppel's description. A.A., axillary artery; X., arteriovenous fistula; A.V., axillary vein; A.V.P., deep axillary vein; B.V.L., lateral brachial vein; B.V.M., medial brachial vein; C.V., collateral vein circulation; C.A., collateral arterial circulation. A description is given in the text.

The third operation was begun at 8:30 p. m., and consisted in a complete extirpation of the arteriovenous fistula. Immediately after isolation of the aneurysm sac, the arm became hyperemic and remained so for a period of twenty-four hours. Pain ceased, and an uneventful convalescence ensued.

I believe that von Oppel was in error in attributing the temporary improvement in the circulation of the arm observed during the course of the second operation to occlusion of the deep axillary vein. It would seem more likely that the pressure of the finger or the operative maneuvers of exposure of the vein resulted in temporary compression of the fistulous tract. I believe that he was also in error in his statement that the patient's condition was improved by the second operation.

The extreme pain which was present between the second and third operations would seem contradictory to this view.

This paper of von Oppel is an admirable record of the principles involved in the treatment for arteriovenous fistula. I am certain that any one who carefully reads this publication of von Oppel will be convinced that Korotkow, who was associated with von Oppel, had a clear conception of the principles involved in the ligation of the vein as a part of the operative procedure in the treatment for arteriovenous fistula. I believe that von Oppel had in mind only the conditions peculiar to arteriovenous fistula when he stated:

So far as I know, up to the present time, there has been no mention of a rôle being played by the veins in relation to the origin of gangrene of the extremities.

Von Oppel's conception of the relationship of venous obstruction to the conditions associated with arteriovenous fistula is more clearly expressed in the following statement:

When it is realized that the function of the collateral arterial circulation can be and is disturbed by the veins which suck arterial blood through the aneurysmal sac, then it is easy to draw the conclusion that those operative procedures should be chosen which will remove the aspirating effect of the veins upon the arterial blood, in other words, that procedure will be correct which, in the region of the aneurysm, *separates the bed of the arterial blood from that of the venous blood.*¹²

In the separation of the bed of the arterial blood from that of the venous lies the principle of safe operative treatment of arteriovenous aneurysm of the peripheral vessels.

I believe that the first appreciation of the fundamental principles underlying therapeutic venous occlusion for arterial obstruction without arteriovenous fistula is to be found in the records of the experiences with an operative procedure opposite in nature to the operative method applicable to arteriovenous fistula.

In 1902, Carrel and Morrel attempted some experiments, the object of which was the reversal of the circulation in an extremity. During the same year, both Satrustegui¹² and Jaboulay attempted to produce a fistulous opening between the femoral artery and the femoral vein with the idea that this procedure would be beneficial in patients in whom gangrene of the extremity seemed imminent. In 1906, Carrel¹³ showed conclusively that reversal of the circulation was possible in the experimental animal. In the same year, Hubbard¹⁴ of Boston and Lilienthal¹⁵ of New York reported instances of the application of this operative procedure for the treatment of impending gangrene of an extremity.

12. Satrustegui: Bull. med., Madrid, 1902.

13. Carrel and Guthrie: Ann. Surg. 43:203, 1906.

14. Hubbard: Ann. Surg. 44:559, 1906.

15. Lilienthal: Ann. Surg. 45:1, 1907.

In 1908, Wieting¹⁶ of Constantinople described the indications, the operative technic and the results of an operation intended to reverse the circulation in the arteries and veins of an extremity in instances of arterial occlusion. In spite of the priority of the publications of Carrel, Hubbard and Lilienthal, this operation is still referred to in the literature as the Wieting operation. Following Wieting's report, there was much discussion as to the value of this operation as a therapeutic measure and as to the possibility of its actually resulting in a reversal of the direction of blood flow through the capillaries. The controversy between Wieting and Coenen¹⁷ was particularly spirited. Wieting enthusiastically contended for the success of the operative procedure and discredited all experimental work which led to conclusions contrary to his own. The result of the controversy was the stimulation of a wider interest in the problems concerned.

The technic of the operative procedure which stimulated so much interest in the surgical treatment for diseases of the circulation of the extremities was variously modified. The original procedure consisted in a complete division of both the artery and the vein, transposition of the stumps of the vessels and end-to-end sutures. The operative technic was changed to one in which the vein was ligated, the artery divided, the distal stump of the artery ligated, and an anastomosis made between the proximal arterial stump and the vein distal to the ligation. The same result was accomplished by another modification of the operative technic, in which a lateral anastomosis of the artery and vein was made and the vein ligated proximal to and the artery distal to the fistulous opening. The final modification of the operation consisted of a lateral anastomosis of artery and vein and ligation of the vein proximal to artificial arteriovenous fistula.

The result of the interest in these operative procedures was the stimulation of a considerable amount of experimental work, of which some of the most interesting and valuable contributions have been overlooked because of their publication in the Russian language. It would seem, however, that von Oppel and his assistants were the first to call attention to the possibility that all the beneficial results which had followed the various operative procedures for reversal of the circulation had been due to venous obstruction rather than actual reversal of the circulation. Von Oppel, therefore, advanced the idea that the logical procedure in instances of arterial obstruction was the ligation of the vein. As evidence of the truth of this, he¹⁸ reported in 1913 six instances of marked anemia of the lower extremity in which definite evidences of improvement had followed ligation of the popliteal vein.

16. Wieting: *Deutsche med. Wchnschr.* **34**:1215, 1908.

17. Coenen: *Zentralbl. f. Chir.* **38**:106, 1911.

18. Von Oppel: *Vrach. Gaz.* **20**:303, 1913.

It is to this report that Makins referred in his Hunterian Oration in which he first advocated the ligation of the vein in instances of arterial obstruction without arteriovenous fistula.

It would seem, therefore, as if the idea of therapeutic venous occlusion for simple arterial obstruction grew out of the experiences with an operative procedure which in reality is a procedure quite opposite to that usually considered the origin of the idea.

In passing it may be said that no better evidence of the lack of knowledge of the elementary principles of the circulation of blood could be cited than the fact that a condition recognized as the cause of gangrene

Fig. 5.—The various modifications of the operative procedure designed to reverse the circulation of an extremity.

was produced as a means of its relief. It is also worth while to call attention to the fact that during this period of awakened interest in therapeutic venous occlusion, there was apparently no clearcut definition of the different conditions to which it was deemed applicable. Von Oppel revealed his conception of the abnormal conditions of the circulation due to arterial obstruction when he wrote:¹⁹

As is known, angiosclerotic gangrene begins because of the lack of arterial blood supply. In instances of diminished circulation of an extremity, if the extremity is elevated, it becomes deathly pale and the characteristic ischemic pain

19. Translated from the Russian by Mr. Myer Epstein, Vanderbilt University Medical School and abstracted by the author.

ensues. If the extremity is then put into dependent position, hyperemia appears and the pain disappears. Why is this so? Observation of the blood pressure in the thigh in a patient with impending gangrene shows the blood pressure to be 30-50 mm. of mercury, which is about that of collateral arterial pressure after occlusion of the major arterial trunk. The blood pressure is, therefore, sufficiently low so that the hydrostatic pressure from the horizontal position is enough to cause cessation of the circulation. Maniewsky's experiments show that the Trendelenburg position may cause the pressure in the femoral vein to diminish nearly to zero. This is true if the arteries are healthy and the extremity is comparatively short. It is clear that with a diminished inflow of blood, this phenomenon would be exaggerated. Diminution in the venous pressure will result in a sucking into the vein of the collateral arterial blood supply and thus divert it from reaching the more distal aspects of the extremity. When the extremity is placed in the dependent position the weight of the blood in the arterial tree will be sufficient to cause a dilatation of the arteries, and the venous pressure will be increased. The advantage of the dependent position in preserving the nutrition of the tissues in patients with incipient gangrene is shown by the fact that these patients always prefer the extremity to be in the dependent position. In some instances, the patient cannot even endure the horizontal position. Both clinical and experimental observations show that ligation of the vein is associated with an increase in the pressure in the veins and arteries.

On these observations, I have recommended the ligation of the vein as a palliative procedure in instances of ischemic conditions, realizing that this procedure produces a reduction²⁰ in the circulation but is beneficial to the patient, at least for a time, in preventing the pain and helping to limit the gangrene. Ligation of the vein is beneficial not because the outflow is reduced, but because reduction in the outflow favorably influences the arterial circulation.

EXPERIMENTAL WORK

It would be impossible to review all the experimental work which has a bearing on therapeutic venous obstruction. Many important observations bearing on this subject are contained in the records of researches, the purpose of which was the study of other problems in the circulation. A brief review of a few of the most recent publications, devoted exclusively to the simultaneous ligation of the vein as a therapeutic measure in arterial obstruction, is sufficient for the object of this paper.

At the Conference of Inter-Allied Surgeons in Paris in 1917, van Kend²¹ reported some experimental work, the conclusions of which were reported by Makins as follows:

In carrying out a series of experiments made with the object of determining the indications and physiological basis for transfusion of blood, I have had the opportunity of measuring the blood pressure in limbs of which the main artery had been ligatured. The blood pressure was taken successively after the artery alone had been tied and again when ligature of the vein had been superadded.

20. In "reduction of the circulation," I believe that von Oppel had in mind the entire extremity and not its most peripheral aspects.

21. Van Kend: *Compt. rend. conf. chir. internat.*, Paris, 1917, p. 348.

My observations confirm the view that has been expressed by Sir George Makins. In fact, plethysmographic tracings demonstrate clearly that a slight rise in the blood pressure in the limb follows the application of a ligature to a main vein after previous ligature of the artery. It appears then from the standpoint of the physiologist that to leave the main vein viable after occlusion of the main artery of a limb diminishes what may be called the residuary blood pressure maintained by the collateral circulation. If the contribution of the collateral circulation is allowed to remain with the main vein intact it is natural that the residuary blood pressure should fall. If this view be adopted, ligature of the vein as well as the artery should be recommended in order to retain the blood supplied in longer contact with the tissues. Thus the most satisfactory conditions for the maintenance of the nutrition of the organs are provided, because the obstacle to the return circulation provided by the ligature retains the blood for a longer period in the member.

Makins also quoted from a private communication received from Major Hamilton Drummond in which Drummond reported having found, from experiments made on loops of intestine of the cat, that gangrene more frequently followed ligation of the arteries alone than if both the arteries and the veins were obstructed.

The only experimental work which Halsted reported in his discussion of therapeutic venous occlusion for the relief of symptoms following arterial occlusion is the result of six experiments in which the blood pressure in the arteries distal to the arterial occlusion was measured before and after occlusion of the concomitant vein. It was found that venous obstruction was always followed by an increase in the intra-arterial tension and that release of the venous occlusion was followed by a diminution in the intra-arterial pressure.

Experimental work which was undertaken for the study of other physiologic changes than those of blood pressure was reported by Brooks and Martin²² in 1923. In these experiments, it was found that the blood pressure in the artery distal to the point of occlusion was increased by the occlusion of the vein at the level of arterial occlusion. The pressure in the vein distal to the point of occlusion was increased relatively more than the pressure in the artery. The effect of the venous obstruction on the volume flow of blood in the tissues was studied by means of determinations of temperature in the tissue. It was found that after occlusion of the artery the temperature of the tissues, supplied by this vessel, was diminished and that further diminution occurred if the concomitant vein was also obstructed. From these facts, it was concluded that in instances of arterial obstruction occlusion of the concomitant vein resulted in an increase in intravascular blood pressure of all the vessels distal to the occlusions, and that the diminution of the

22. Brooks, B., and Martin, K. A.: Simultaneous Ligation of Vein and Artery. *J. A. M. A.* 80:1678 (June 9) 1923.

volume flow of blood which resulted from the arterial occlusion was further diminished by the venous obstruction.

The effect of ligation of the concomitant vein on the incidence of gangrene in arterial obstruction was studied in a comparatively large series of experimental animals. It was found that the incidence of gangrene was decidedly less in those instances of obstruction of both artery and vein than in those instances in which the artery alone was obstructed.

From these experiments it was concluded that obstruction of the concomitant vein in the presence of arterial obstruction resulted in an increase in intravascular pressure but in a decrease in volume flow of blood through the tissues. The diminished incidence of gangrene, in spite of the diminished volume flow of blood, was attributed to the beneficial effects of the increased intravascular tension which probably operated in such a way as to produce a more equitable distribution of the blood flow.

More recent experimental work by Holman²³ and by Theis²⁴ has confirmed the effects of concomitant ligation of the vein on the blood pressure, but both Holman and Theis have reached a conclusion contradictory to that of Brooks and Martin concerning the effect of concomitant venous obstruction on the volume flow of blood. I believe that both of these investigators are in error in that they have not correctly interpreted their experimental observations. Both of these investigators have used the same method for estimating the effects of obstruction of the vein on the volume flow of blood. This method consists in observing the flow of blood from a cannula placed in the artery distal to the point of arterial obstruction. It was found that the amount of blood which flowed out through the cannula was increased if the vein was obstructed. This fact was interpreted by both of these investigators to indicate an increase in volume flow of blood through the tissues after occlusion of the vein. It would seem obvious that the increased flow of blood from the cannula in the artery distal to the obstruction would be the result of an obstruction to the outflow of blood and the corresponding increase in intravascular pressure and would thus be an evidence of diminished rather than increased volume flow through the tissues.

Other physiologic changes resulting from intentional occlusion of veins have been studied experimentally. Holman and Edwards, from experiments on dogs, found that the arterial blood pressure distal to the point of arterial obstruction was increased relatively more if the vein

23. Holman, E., and Edwards, M. E.: *New Principle in Surgery of Large Vessels*, J. A. M. A. **88**:909 (March 19) 1927.

24. Theis, F. V.: *Ligature of Artery and Concomitant Vein in Operation on Large Blood Vessels*, Arch. Surg. **17**:244 (Aug.) 1928.

was occluded at a level nearer the heart than at the site of the arterial obstruction. These investigators believed that the occlusion of the vein at this relatively higher level caused an increase in the peripheral resistance of the circulatory bed supplied by the arteries furnishing the collateral branches, and thus caused a diversion of blood through the collateral paths of circulation into the arterial system distal to the point

Fig. 6.—The experimental method used by Holman to determine the effects of ligation of the vein on the volume flow of blood through an extremity. It is obvious that obstruction of the vein at *X* would result in more blood flowing through the cannula. The fact that more blood flows from the cannula is not an indication of an increased volume flow of blood through the capillaries, but is evidence for the truth of the contrary conclusion.

of arterial obstruction. This conclusion is based on the fact that ligation of the vein at a higher level causes more increase in the intra-arterial pressure distal to the arterial occlusion than ligation of the

vein at the same level of arterial occlusion. This possibility was also considered by Brooks and Martin, but no experimental evidence could be found to substantiate it. As a matter of fact, their observations were such as to lead them to believe that this diversion of blood flow did not actually occur.

The effects of venous occlusion on the number and size of the paths of collateral arterial circulation about a site of arterial obstruction have been studied experimentally by Pearse²⁵ and by Theis.²⁴ Pearse found that ligation of the artery and vein was always followed by a richer collateral vascular bed than that following obstruction of the artery alone. On the other hand, Theis found that the collateral circulatory bed was better developed in those instances in which the artery and vein were occluded only if the determination was made immediately after the experimental vascular occlusion. In observations on the experimental animals, after a period of three weeks, the vascular bed was richer in those instances in which the artery alone was occluded.

The different results obtained by these investigators must have been due to a difference in the experimental methods used. It is worth while, however, to call attention to the fact that the size of blood vessels as determined by injection is not a reliable index of the actual volume flow of blood through tissues, and also to the fact that the condition of the circulatory bed three weeks after a sudden arterial occlusion is not necessarily important in the study of the cause of gangrene.

The conclusions from all observations concerning the physiologic effects of obstruction of a vein in the presence of arterial obstruction may then be briefly summarized as follows:

1. All observers agree that ligation of the concomitant vein in the presence of simple arterial obstruction is followed by an increase in the blood pressure in both the veins and the arteries distal to the level of obstruction.

2. Both experimental and clinical experience indicate that the incidence of gangrene is diminished.

3. In the attempts to explain the beneficial effects of therapeutic venous obstruction on the manifestations of arterial occlusion without arteriovenous fistula is found the confusion of ideas. Some are content to assign the beneficial effects to the "retention of blood in the tissues" or to a "restoration of the balance in circulation." With a clear conception of the fundamental principles of circulation of blood and the specific conditions under consideration, it becomes evident that the important differences of opinion, in regard to the effects of therapeutic venous obstruction, lie in the different views held concerning the influence of this procedure on the distribution of the volume flow of blood.

25. Pearse: *Ann. Surg.* 86:850, 1927.

It would seem as if all observers, except Brooks and Martin, believed that ligation of the vein was beneficial because this procedure increased the volume flow of blood in the capillary bed of the distal aspect of the extremity. If such is true, then the fundamental principles involved may be the same in therapeutic venous obstruction whether it is applied as treatment for arteriovenous fistula or for simple arterial obstruction.

If the conclusions drawn from the experiments reported by Brooks and Martin and other unpublished experiments of mine are true, the beneficial results of therapeutic venous occlusion in instances of simple arterial occlusion are not because blood flow is increased in the distal aspects of the extremity, but because the blood flowing through the distal aspect of the extremity is more equably distributed in the capillaries and is under greater tension in all the vessels. The actual amount

Fig. 7.—The different ideas which have been expressed as to the effect of simultaneous ligation of the vein on the volume flow of blood. In these diagrams the amount of the volume flow of blood in the capillary beds of the different aspects of the extremity is indicated by the vertical height of the rectangles. The distribution of the blood in the capillaries is indicated by the network in the rectangular spaces. The intracapillary pressure is indicated by the relative thickness of the lines of the network. In *A* it will be seen that ligation of the vein is followed by an increase in the amount of volume flow and intracapillary pressure in all aspects of the extremity. In *B* ligation of the vein is followed by a diminution in the volume flow through the proximal aspect of the extremity and an increase in the volume flow through the distal aspects of the extremity. The intracapillary pressure is increased in all aspects, and no change is indicated in the distribution of the flow in the capillaries. In *C* it will be noted that the volume flow of blood is diminished in all aspects of the extremity after ligation of the vein. The intracapillary pressure is increased in all parts. The distribution of the flow in the capillaries of the most distal aspect of the extremity before ligation of the vein is irregular, while after ligation of the vein it is homogeneous.

of the blood flowing through the distal tissues of the extremity is diminished by ligation of the vein. The principles involved in this view are entirely different from those concerned in therapeutic venous occlusion in the presence of arteriovenous fistula.

From a consideration of these facts, it would seem as if any existent difference of opinion was a matter of only academic interest, and that from the purely practical point of view the indications for therapeutic venous obstruction are clearly defined. Such is not the case. The conditions so far discussed have been considered from the point of view of their being fixed or unchanging. In the clinical application of the principles of therapeutic venous occlusion for arterial obstruction, it must be borne in mind that the situation is made more complex because the conditions are constantly changing and thus the remote

Fig. 8.—The differences in the conditions attending the development of collateral circulation in arteries (*A*) and in veins (*V*). It will be noted in *A* that the collateral circulation is from a branch proximal to the arterial obstruction through the collateral anastomotic branch (*C*) and thence in the reversed direction through the artery forming the distal aspect of the collateral arch. It is obvious that the amount of blood which passes through the collateral arch may continue to increase with an increase in the cross-section area of the arch. In *V* it will be noted that the collateral circulation about the obstruction is prevented from developing through the channel *Z* on account of the action of the valves. If it develops through the channel *Y* and this vessel subsequently enlarges, then its valves become incompetent.

as well as the immediate effects must be considered. In sudden arterial obstruction, from a wound or embolus, the greatest interference with the blood supply is immediate and without further complications, the blood flow through the anemic tissues may be expected to increase with the development of the collateral circulation. In instances of chronic arterial obstruction due to progressive obliterative arterial disease, there

may be a constant or intermittent change in the opposite direction. Also the amount of venous obstruction which is produced by the ligature of a vein does not remain fixed. Paths of collateral circulation develop about points of venous obstruction. Important differences exist between development of collateral circulation in veins and in arteries.

The sole source of energy for the propulsion of the blood stream through the arteries is the contraction of the heart. The development of collateral circulation about a point of arterial obstruction is necessarily associated with a reversal of the direction of flow through the artery constituting the distal aspect of the collateral arch.

Fig. 9.—The effect of simultaneous ligation of the vein in the presence of arteriovenous fistula. In the conditions represented in the diagram, it will be seen that with ligation of the vein at *X* with the competence of the valve at *D* only such blood can pass through the fistula as could return to the heart through the vein (*C*). This would be true only if the pressure within the dotted area was insufficient to cause a breaking down of the valve at *D*. Subsequent increase in the pressure in the dotted area or dilatation of the vein at *D* would open new channels for the return flow of blood passing through the fistulous opening. This diagram illustrates a principle which may explain the temporary "improvement" sometimes observed in the treatment of arteriovenous fistula by simple proximal ligation of artery and vein. This condition may have been present immediately after the second operation in von Oppel's case.

The capacity of the collateral arterial circulation is therefore determined solely by the cross-section area of the collateral anastomotic branches.

The energy for propulsion of the blood through the veins is derived from three sources: 1. Diastole of the right side of the heart aspirates

blood from the adjacent large veins. 2. The blood may also be propelled through veins by the force of the left side of the heart transmitted through the arteries and capillaries. 3. In veins with valves, the flow of blood is accelerated by the alternate compression and relaxation of the vein by motion of the adjacent tissues. The operation of this factor is dependent on the fact that the valves in the vein permit the flow of blood in only one direction. The last factor is of great importance in propelling blood through veins of the extremity.

If collateral circulation in veins is considered in the light of these facts, it is obvious that a venous collateral circulation cannot develop by the reversal of the direction of the current through veins with competent valves. Furthermore, if the collateral circulation is through veins in the normal direction, then dilatation of these veins renders the valves inefficient.

These statements are in accord with clinical experience. If an extremity successfully passes through the immediate critical stage following simple arterial occlusion, a satisfactory permanent recovery may be anticipated. If, however, the manifestations of severe venous obstruction develop, convalescence is prolonged and often never complete.

It would seem, therefore, as if the remote effects of therapeutic venous obstruction must be taken into consideration. In other words, ligation of a vein might be the means of averting gangrene but the cause of subsequent chronic venous stasis. The clinical experience available is not sufficient for drawing definite conclusions. A letter from Sir George Makins, written in May, 1922, stated:

I have seen some swollen extremities and varicose veins amongst the war pensioners, but in all the cases I have had the opportunity of examining, the injury to the vessels was accompanied either by very extensive wounds with loss of substance, or fracture of the femur or pelvis. I have not been able to regard these cases as a fair test, and no uncomplicated case of ligation of artery and vein with unsatisfactory after consequences has come under my notice.

Still, I think the question of the ultimate condition of the limb must be considered undecided.

My own clinical experience leads me to believe that venous occlusion of an amount sufficient to be of value in the prevention of gangrene is often followed by manifestations of venous stasis from which convalescence is prolonged or incomplete.

From a consideration of all evidence available, I believe that the following statements are substantiated by the results of experimental study and clinical experience.

A. In operations for the cure of arteriovenous fistula, the vein should always be ligated in any of the following conditions: (a) If in the course of an operation the artery has already been ligated and

it is then found that the complexity of the condition present makes it seem beyond the skill of the operator to attempt to close the fistulous opening, or if the surgeon is uncertain of the success of his attempts, then ligation of the vein proximal to the fistula is imperative (fig. 9a). (b) If an arteriovenous fistula has existed for a relatively short period and if it is necessary to obliterate the artery in order to close the fistula, then ligation of the vein is preferable in most instances and is always indicated if the artery is either the popliteal or the axillary. If an arteriovenous fistula is of long duration, the collateral arterial circulation is so abundant that even though it is necessary to obliterate the main artery in closing the fistula, ligation of the vein is unnecessary and even contraindicated. (c) There is a certain amount of justification in the view that ligation of the vein is always preferable in the treatment for arteriovenous fistula because of the danger of pulmonary embolism from thrombosis at the site of repair of the fistulous opening in the vein. I do not subscribe to this view.

B. In progressive arterial degenerative disease, associated with arterial obstruction, ligation of the vein is at most a palliative measure, the beneficial effects of which only occasionally justify its employment.

C. In instances of sudden arterial occlusion, therapeutic venous obstruction finds its most valuable applications.

If from traumatism or in the course of any operation it becomes necessary to ligate a large artery, simultaneous ligation of the concomitant vein should always be considered. If the artery ligated is the popliteal or axillary, I believe that ligation of the like named vein is definitely indicated. In instances of ligation of the femoral or brachial arteries, I am inclined to believe that simultaneous ligation of the vein in reality makes little or no difference. If the common femoral artery is ligated, I am inclined to believe that it is wiser to close the wound without ligating the vein, to watch the extremity carefully for signs of impending gangrene, and to ligate the vein only after such signs are evident. From my own experience, I believe that ligation of the common iliac artery is not an indication for ligation of the common iliac vein.

CONCLUSION

Simultaneous ligation of the vein is not to be considered the preferable procedure in all arterial ligations. It is to be applied only in those instances in which without ligation of the vein gangrene would be expected. In these instances, the probable immediate beneficial effects in preventing gangrene must be balanced with the possible remote ill effects of chronic venous stasis.

THE STRUCTURE OF BONE

The microscopic anatomy of bone has been carefully studied by the older anatomists and histologists. All the controversial points have not been settled, and many questions still remain open. However, judging from the limited knowledge of bone structure that is prevalent now, except among those especially interested in the subject, one would think that this work had not been done. Perhaps there is a correlation between the dearth of recognized pathologic exposition of bone conditions and the lack of dissemination of histo-anatomic knowledge of bone. With the development of surgery of the bones and joints in recent years, many pathologic conditions, heretofore recognized only clinically, have become available for pathologic study. This work will be done mainly by surgeons and surgical pathologists, who will obviously base their interpretations on deviations from the normal. Since no

detailed study of the structure of bone exists in American literature, it was thought that such an exposition might prove helpful to surgeons who are interested in bone as a tissue. The possibilities of improving the character of the work done on bone will be enhanced by a knowledge of the nature of the tissue.

Another reason why the study of bone is approached hesitatingly is that its histologic preparation is believed to be difficult. In another paper,¹ I have given directions for the preparation of bone for histologic study, and many of the methods could be applied to pathologic bone with great advantage.

In this paper, I am emphasizing that phase of bone structure which is least discussed. An effort is made to describe the general architecture of bone, and its fibrillar constitution is particularly emphasized. Osteoblasts have been only casually referred to, for when bone is already formed, they are structurally unimportant. The canal systems and their anastomoses have been discussed only in passing, and a description of the circulation has been omitted since it is unnecessary for an understanding of the structure of bone. The bone cells have been described in regard to their form but not in regard to function. Furthermore, these subjects are important enough to warrant special consideration.

COARSE-FIBERED OR PRIMARY BONE

Mammalian bone consists of collagen fibers and cells which are embedded in a cement substance containing calcium salts. There are essentially two types of bone, depending on the character and arrangement of the collagen fibers. In the bone which characterizes the skeleton of the human fetus and the new-born, the fibers are irregular and mainly coarse, and the cells are large, numerous and irregular. This type of bone practically disappears by the fourth year of life, and it is replaced by typical adult bone, which has for its distinguishing character fine fibers in lamellar arrangement. In different species of lower mammals the time interval, during which the coarse-fibered bone is replaced by lamellar bone, varies.

Phylogenetically, coarse-fibered bone is the older and more primitive bone tissue. Some of the lowest vertebrates retain this type of bone for their adult skeleton, and it represents the greatest part of their periosteally formed bone. Coarse-fibered bone is the type of bone generally seen in ossified fibrous tumors and in osteogenic sarcomas, and it is the first bone formed in the repair of a lesion of the bone even in the adult. In short, whenever new bone is being formed, except in the case of the normal reconstruction that goes on constantly in lamellar

1. Jaffe: Methods for the Histologic Study of Normal and Diseased Bone. Arch. Path., to be published.

bone, it is first formed as fiber bone, which may later be replaced by lamellar bone. Coarse-fibered bone persists in adult man in those places in which tendons are attached to bone and, according to Meyer, in the bony capsule of the labyrinth of the ear. Sometimes small nests of fiber bone with thick Sharpey fibers may be seen in adult cortical bone.

When bone is first formed in the fetus, either as membrane or endochondral bone, it consists of trabeculae containing coarse fibers and cells between which lies a loose, vascular, connective tissue in which the primitive marrow develops. The structure of coarse-fibered bone may be studied in older fetuses and in the new-born in which it is laid down beneath the periosteum or is deposited on the calcified cartilaginous trabeculae in endochondral ossification. If one examines a cross-section of the diaphysis of a tubular bone or the mesodermal bone of the jaw of a 6 months fetus, it shows numerous haversian canals which are only rarely circular in cross-section, being generally somewhat elongated. Wide anastomoses are often seen between them. Irregular bony trabeculae lined by osteoblasts are present between the canals. The main direction of the haversian canals is longitudinal, as it is in adults (fig. 1). Immediately about the haversian canals the bone is least dense, but the bone between two adjacent haversian canals is more dense. Here the fiber bone consists of closely meshed, interlacing and decussating fiber bundles in which numerous irregularly disposed bone cells are embedded. Most of the fibers are thick and coarse. The fiber bundles measure from 2 to 27 microns across, but average from 12 to 15 microns. The larger bundles consist of groups of smaller bundles. The bundles are separated from each other by a layer of cement substance, or by some disordered fibrils. The marked irregularity of arrangement of these fibers is as much a characteristic of this bone as the thickness of the fibers. The mass of thick decussating fibers between two haversian canals was designated by Gegenbaur² as *Wurzelstock* (fig. 2).

The coarser fibers of primary bone are better known as Sharpey fibers. While present in great numbers in the bone of the fetus and new-born, few are contained in adult bone. They were described by Sharpey in adult bone in the sixth edition of Quain's anatomy and have also been studied extensively by Mueller³ and Koelliker.⁴ Developmentally, their origin is different from that of the fine fibrils of lamellar

2. Gegenbaur: Ueber die Bildung des Knochengewebes, *Mitt. Jen. Ztschr. f. Med. u. Naturwiss.* 1:341, 1864; 3:205, 1867.

4. Koelliker: *Handbuch der Gewebelehre*, 1889, vol. 1.

bone, since they are derived from the periosteum. Von Ebner⁵ and others described them as connective tissue and collagenous fiber-, and Koelliker expressed the belief that some of them, particularly the thicker ones, may be partially calcified. In the fetus and the new-born, they are best seen in longitudinal sections of the periosteal trabeculae of tubular bones. By the fourth year, their appearance and number are the same as those in adult bone.

Fig. 1—Part of a cross-section through the diaphysis of a long bone of a 6 months fetus, showing fibrous periosteum, osteoblastic periosteum, irregular trabeculae lined by osteoblasts and large haversian spaces with primitive marrow.

Numerous anastomosing bone cells are embedded between the fiber bundles, either singly or in groups. These bone cells are larger than those of adult bone. The lacunae, therefore, are larger and somewhat irregular. The processes of the bone cells of coarse-fibered bone are shorter, thicker and fewer than those of adult bone cells, and the canaliculi are correspondingly shorter and wider. If the lacunae of

⁵ Von Ebner: Ueber den feineren Bau der Knochensubstanz. Sitzungsab. d. Akad. d. Wissensch. 71-72:49, 1875.

the bone cells are closely packed, they may fuse and produce large spaces into which parts of the fiber bundles or groups of disordered fibrils may enter. In recently formed fiber bone, the cells are more numerous and newly formed trabeculae underneath the periosteum may consist of so many cells that the bone has a fenestrated appearance. This is also true of the fiber bone removed from the neighborhood of healing fractures, examination of which will show trabeculae that consist preponderantly of irregularly dispersed bone cells, held in the meshes between matted fibers (fig. 3).

A section through a long bone of an infant in the region of endochondral ossification shows the difference in structure between the

Fig. 2.—The thick fibers of the Wurzelstock between the haversian canals. Frozen section from skull of an infant, aged 12 weeks. Bielschowsky silver stain.

primary coarse-fibered bone deposited on the calcified cartilage cores and the primary coarse-fibered bone formed by the periosteum. Primary endochondral bone is similar in fibrillar structure to the periosteal primary bone, except that, as has been observed by von Ebner, the thick centrally placed mass which was described as Wurzelstock by Gegenbaur is absent, its place being occupied by calcified cartilage cores. The line of junction between the cartilage core and bone is irregular and corresponds in many respects to the cement lines of adult bone. Otherwise, cement lines are practically absent.

In man the character of the fiber bone rapidly changes, and soon after birth a cross-section through the diaphysis of some of the bones will show that the haversian canals have narrowed considerably in

diameter, that there is a tendency for the fibers to be disposed more regularly, particularly about the canals, where the fibers are thinner, and that the bone cells near the canals appear more like the bone cells of lamellar bone. A few thick fiber bundles may course through the fibrils arranged around the haversian canal and may enter the canal.

The problem that is still controversial is the part that osteoblasts play in the formation of fiber bone. Many believe that coarse-fibered bone results from a bony transformation of mesenchymal or embryonal connective tissue, during which calcium salts are deposited between the

Fig 3—Newly formed trabeculae under the periosteum showing numerous irregularly disposed bone cells. This should be compared with figure 5.

fibers, and in the formation of which osteoblasts play no part. They believe that in the formation of this bone the connective tissue cells become transformed into bone cells. There are others who believe that the primary bone develops everywhere from the mesenchyme through the medium of osteoblasts, and not indirectly, as already described above, from calcification and ossification of connective tissue. Lubosch⁶ was in full agreement with the opinion of Schaffer⁷ that all bone arises

⁶ Lubosch Die Osteoblasten und ihre Metamorphose, Ztschr. f. mikr. Anat. 12:279, 1928

⁷ Schaffer: Die Verknöcherung des Unterkiefers und die Metaplasiefrage, usw., Arch. mikr. Anat. 32:266, 1888

through the participation of osteoblasts which are specific differentiated bone-forming cells of the embryonal mesenchyme. I am in accord with this view so far as it pertains to skeletal bone, and believe that all the embryonal primary bone is of osteoblastic origin. But how the osteoblasts form bone, that is, what the relation between the osteoblasts, fibrils, cement substance and the deposition of calcium is, are involved questions, the answers to which are not necessary for an understanding of the structure of fiber bone.

FINE-FIBERED OR LAMELLAR BONE

Lamellar bone replaces the original coarse-fibered bone, and by about the fourth year nearly the entire human skeleton consists of lamellar bone. Heuler,⁸ in studying cross-sections of the shaft of the human femur and humerus, found that by the eleventh year the adult structure is reached and maintained with no change from then on. It has been mentioned that coarse-fibered bone is the more important in the skeleton of a vertebrate, the lower it stands in the animal scale and the smaller its body. Gebhardt expressed the belief that the degree of formation of lamellar bone is related directly to the size of the skeleton, but of this there is some doubt.

Previous to birth the vascular spaces in the bone cortex are relatively large, and a coarse reticular structure is present. The size and shape of the vascular spaces at this time vary with the part of the shaft examined. The spaces are larger the nearer they are to the epiphyseal cartilage plate, and in the middle of the shaft of the diaphysis the spaces nearer the periosteum are larger. The primary haversian canals of coarse-fibered bone are the first spaces formed when bone is produced by the periosteum. In the course of development, many of these primary canals under the periosteum become confluent because of resorption of their walls and become the longer and more irregular haversian spaces. Shortly before and after birth osteoblasts deposit lamellae of fine-fibered bone on the coarse-fibered walls of these spaces, forming haversian systems. A haversian system consists of a central canal with bone deposited concentrically about it. At the same time, new trabeculae of coarse-fibered bone are formed subperiosteally. *A* and *B* of figure 4 are cross-sections through the middle of the shaft of an infant, aged 12 weeks, showing subperiosteal fiber bone with wide subperiosteal haversian spaces. Deeper in the cortex the canals have become reduced in size and some are surrounded by lamellar bone, though between the canals considerable coarse-fibered bone is still present. These first and

8. Heuler: Korrelation zwischen Alter und Knochenstruktur, *Ztschr. f. Zellf. u. mikr. Anat.* 7:41, 1928.

true haversian lamellar systems are also of temporary nature, and are resorbed and serve for the formation of new haversian systems. The process of formation and dissolution continues until the adult stage is reached, and even then a constant but slow reconstruction is continually taking place.

Beneath the periosteum, lamellar bone is laid down, and the surface of the bone finally consists of a series of lamellae. But various authors

Fig 4—4, part of a cross-section of the diaphysis of a long bone of an infant, aged 12 weeks, showing wide subperiosteal haversian spaces underneath a thin layer of subperiosteal bone. Deeper in the cortex, the smaller haversian canals are seen. Carmine and Weigert's fibrin stain. B, part of cross-section through another long bone of the same infant. have described the first appearance of subperiosteal lamellar bone at different times. In long bones Schwalbe⁹ found fiber bone beneath the

⁹ Schwalbe Ueber postembryonales Knochenwachstum, Sitzungsber d med naturw Gesellsch zu Jena, 1877, p 11

periosteum until the fourth year. Koelliker reported subperiosteal lamellar bone as early as the first year after birth. Recently, authors have described subperiosteal lamellar bone in the first months after birth. I saw no subperiosteal lamellae in cross-sections through the shafts of two long bones of an infant, aged 12 weeks, though lamellar bone was present deeper in the cortex. On the larger endochondrally formed trabeculae in the marrow cavity, some lamellar bone is seen after birth.

General Structure of Lamellar Bone.—When an adult tubular bone is sawed open longitudinally, parts of it are seen to be dense and compact in texture and other parts, spongy. Accordingly, two forms of adult osseous tissue are distinguishable, compact and spongy bone. On closer examination, however, especially with the aid of a magnifying glass, it will be found that bone is everywhere more or less porous, and that the difference between compact and spongy bone depends in part on the different amounts of calcified tissue compared with the size and number of open spaces in each. The cavities are small in the compact parts of the bone, with much dense bone between them, while in the spongy texture the spaces are large, and the intervening bony partitions are thin and slender. When both compact and spongy bone are present, as, for instance, in the upper end of a tubular bone, there is no abrupt limit between the two; they pass into one another by degrees; the haversian spaces of the compact bone widen out, and the reticulations of the cancellated bone become closer as they approach each other.

In all bones, the outside is compact and forms a shell or crust of varying thickness, while the spongy bone is contained within. In a long bone the large round ends are made up of spongy tissue with only a thin coating of compacta; in the hollow shaft, on the other hand, spongy bone is scanty or absent, and the walls are formed of compact bone, which increases in thickness toward the middle, at which point the girth of the bone is usually least. In flat bones, such as those of the skull, the compact tissue forms two plates or tables, enclosing between them the spongy texture, which in such bones is named diploe. The short round bones, as the bones of the wrist, are spongy throughout, except at their surface, where there is a thin crust of compact substance. In the irregular or mixed bone, as, for example, a vertebra, the two types of bone have the same general relation to each other, but the relative amount of each in different parts, varies.

THE COMPACTA

A cross-section of the cortex of a bone shows that there are several ways in which the lamellae are arranged in the compacta. Some are deposited about blood vessels, as the haversian lamellae, to form the

haversian systems, and others do not surround blood vessels but are deposited by periosteum or endosteum, and are known as the outer and inner concentric or ground lamellae. In addition there are the interstitial lamellae which fill in the spaces between the haversian systems (figs. 5, 6 and 7).

In making comparative studies, it becomes evident that the structure of the compacta varies considerably. For instance, the structure was found to be quite different in various segments of the same circumfer-

Fig. 5.—A ground disk of the compacta of the diaphysis of a long bone, showing the outer ground lamellae, haversian systems and interstitial lamellae.

ence of the diaphysis. It was also found that sections through the shaft of various bones of the same person show varying degrees of development of the ground, interstitial and haversian lamellae. Examination of sections of corresponding bones of the rat, guinea-pig and rabbit shows marked variation in the degree of development of the different types of lamellar bone. For instance, a section of the tibia of the rat shows marked development of the outer ground lamellae, the haversian lamellae being few and the inner ground lamellae also being poorly developed. A section through the same bone of a guinea-pig shows better development of the inner ground lamellae, fewer outer

ground lamellae and better developed haversian lamellae. A section through the tibia of a rabbit shows still better development of the haversian lamellae at the expense of the ground lamellae. The dog shows haversian systems still more highly developed, but generally not as irregular as the haversian systems of the human cortex.

The Canals.—A system of preformed canals in the cortex carries blood through the compacta. These canals are known as the haversian canals, Schwalbe's canals, and the communicating canals, some of which are true Volkmann's canals. The haversian canals are found in the compacta, surrounded by concentric lamellae and running longitudinally through the bone. The canals of Schwalbe are found running circum-

Fig. 6.—Another portion of the ground disk, in figure 5, showing the inner ground lamellae below, haversian systems and interstitial lamellae.

ferentially between the ground lamellae or transversely through them. The communicating canals connect the haversian canals; they run transversely or diagonally through the shaft and sometimes, when they are not preformed, are true Volkmann canals.

Haversian Systems.—The haversian system constitutes the basic structural unit of lamellar bone, and a knowledge of its structure and formation is necessary for a clear understanding of the anatomy of adult bone. The formation of this type of bone is ascribed to osteoblasts by all workers who believe that the osteoblasts are bone formers. The osteoblasts deposit the haversian lamellae in layers on the coarse-fibered bone about the walls of the blood vessels in the primary marrow

spaces, thus forming the first haversian systems. The osteoblasts are carried into the fiber bone by the vessels. I agree with those who believe in the specificity of the osteoblasts in the formation of lamellar bone. But how the various constituents of the lamellae are formed opens up questions that I do not want to discuss here, for it involves complex and unsettled problems of bone formation. It seems to me that for the present, it is best to visualize the process of the replacement of coarse-fibered bone by lamellar bone as follows: The osteoblasts about the vessel deposit a layer of osseous material on the fiber bone. As a result, a cylinder is formed which is known as a haversian lamella. As the lamellar bone is deposited on the fiber bone, the latter gives way. The replacement does not occur through the medium of erosion or osteoclasts, but as a process of substitution, in which the fiber bone tacitly disappears. Certain of the chemical components of the fiber bone

Fig. 7.—Segment of a cross-section through the diaphysis of the tibia of a guinea-pig, showing the well developed outer ground lamellae, a narrow zone of haversian systems, and well developed inner ground lamellae. Unstained frozen section of von Ebner decalcified bone.

are utilized by the lamellar bone in the reconstruction. Marchand,¹⁰ in describing the creeping replacement of transplants to which this process is akin, said that when the first lamella is formed, one cell process from each cell of the ring of osteoblasts about the vessel enters it. A few cells leave the original row of osteoblasts, become enclosed in the bone ground substance and become bone cells. The original osteoblastic row is again closed by multiplication of its cells; the process is repeated; a new cylinder is formed between the first cylinder and the blood vessel, just external to the osteoblastic layer. Cells from the osteoblastic layer invade this new bone ground substance, and a second lamella is completed. In this way the haversian columns become stratified structures forming haversian systems made up of haversian lamellae, traversed by a central canal containing vessels.

10. Marchand: Prozess der Wundheilung. Deutsche Chir., 1901, vol. 16.

How the first lamella expands to accommodate the succeeding ones is not made clear in the literature. It is evident that the lamellae are being formed rapidly and that they are not rigid when formed, so that expansion by pressure of the newer lamellae is possible. Also, in the formation of the haversian systems, as the lamellae are laid down, the vessel space is encroached on and the original space is reduced in size, for the haversian canals of normal lamellar bone are generally much smaller than the vascular spaces of fiber bone. Thus the lamellar bone formed about the vessel probably grows centrifugally and centripetally.

The lamellae about the haversian canals are disposed in a ringlike manner, but sometimes they do not extend entirely around the canal. This occurs where one canal is anastomosing with another. In the region of the anastomosis, the lamellae frequently surround the anastomotic vessel. The size and shape of the haversian systems of human bone vary considerably on account of the reconstruction that is constantly taking place. In general it may be said that the widest haversian canals are surrounded by the fewest lamellae, the medium-sized canals by the largest number of lamellae, while the smallest canals also possess thin walls, though they are thicker than the walls of the widest canals.

According to Koelliker, the thickness of the individual lamellae of human bone varies from 4.5 to 11 microns, the average thickness being from 6.7 to 9 microns. Von Ebner gave from 3 to 5 microns as the average thickness of the lamellae, but most were 3 microns thick. My own figures approach more nearly to those of Koelliker. The number of lamellae in each haversian system is, as a rule, from 8 to 15; sometimes only 4 or 5 are present; sometimes from 18 to 22 are seen. The haversian systems constitute most of the thickness of the diaphysis in man and are separated from the periosteum by the outer ground lamellae. Sometimes, the haversian systems even penetrate the outer ground lamellae, while the latter may sometimes enter between the more superficial haversian systems. When inner ground lamellae are present, they separate the haversian systems from the marrow cavity.

Bone Cells.—The lamellae are traversed by the canaliculi and processes of the bone cells while the lacunae, containing the bone cells, are either in the lamellae near the borders or between two lamellae. Most of them are between the lamellae. The lacunae of adult bone are minute elliptic recesses in the bone and extending from them are fine pores or tubes called canaliculi which issue from their cavities. These canaliculi are numerous, slender and relatively straight. They come off from the surfaces of the lacunae, as they may be seen in both longitudinal and cross-sections. They are more numerous in cross-sections. The lacunae present some differences in shape, but in a cross-section they appear irregularly fusiform, for the most part, and lie

nearly in the same direction as the lamellae between which they are situated. That is, the little cavities are flattened and extend conformably with the lamellae. When the bone is cut longitudinally, sections of the lacunae will still appear fusiform and lengthened out in the direction of the lamellae. The canaliculi, on the other hand, pass across the lamellae and communicate with those of the neighboring lacunae so as to connect the lacunae with one another (fig. 8 *A* and *B*). Since the canaliculi of the most centrally placed lacunae open into the haversian canals, a system of continuous passages is established by these tubules and their lacunae, along which fluid may be conducted from the haversian canal

Fig. 8.—*A*, bone lacunae and canaliculi of human bone, showing anastomoses of canaliculi. A longitudinal ground disk mounted in balsam. *B*, lacunae and canaliculi of human bone in a ground disk impregnated with silver according to the method of Matschinsky.

through its surrounding lamellae. It seems probable that the chief purpose of these minute passages is to convey nutrient fluid from the vascular haversian canals through the mass of hard bone that lies around and between them. In a like manner, the canaliculi open into the main marrow cavity and into the marrow spaces between the spongy trabeculae, for the spongy bone also contains lacunae. Each lacuna is occupied by a nucleated bone cell, the walls of which are applied to the inside of the cavity, while branches or tubular protoplasmic processes line the canaliculi and anastomose with intracanalicular branches of similar cells, which occupy neighboring lacunae.

On the surface of the haversian canals osteoblasts are seen, varying in number in the different canals. In adult lamellar bone, just a few are seen.

The Fibrillar Structure of the Haversian Lamellae.—Each lamella consists of innumerable fibrillae embedded in a cement substance, with calcium salts impregnated between the fibrils. Together these elements constitute the ground substance of the bone. If a cross-section of the cortex, in the form of a ground disk or a frozen section, is examined under the polarizing microscope, oil immersion being used, the lamellae present a stippled appearance, each point being 1 micron or less in diameter. The points are closely applied and represent cross-sections of individual bone fibrils. Unless the section is in focus, the stippled appearance is not seen. It may be brought out by pressing the slide vigorously against the stage of the microscope. A longitudinal section of the bone examined in the same way shows a serially striated appearance. In such a section, the striations also represent individual fibrils. Heating the section will bring out the fibrillar structure a little better. The decalcification of bone, hydrochloric acid being used, in no way injures the fibrils.

That the fibrils of bone possess the qualities of fibrils of connective tissue may be seen by the treatment of sections with acetic acid, which causes the fibrils to swell and disappear. If they are countertreated with alkalis the fibrils will reappear, but with overtreatment with alkalis the fibrils will again disappear. Another fact in favor of the similarity of connective tissue and bone fibrils is that collagen can be extracted from both bone and connective tissue.

It is generally believed that the inorganic salts of the ground substance do not become chemically combined with the collagenous fibrils. While a cement substance is believed to be present between fibrils, the unequivocal demonstration of the nature of this material is difficult. Its existence is inferred from the fact that in disks and sections the fibrils are separated and seem to be embedded in a supporting material. Further evidence of the existence of cement substance is the observation of von Ebner that incineration of bone leads to the destruction of the fibrils, but the supporting material remains, and in it air-filled spaces formerly occupied by the fibrils may be demonstrated. The cement substance is supposed to consist of an organic base containing calcium salts. It is apparently the homolog of the cement substance of connective tissue. Since von Ebner made the classic studies of the fibrillar structure of lamellar bone, practically nothing new has been added. However, Henle, and Sharpey before him, had recognized the fibrillar nature of bone.

The uniformity of the arrangement and direction of fibrillar bundles and the delicacy of the fibrils are characteristic of lamellar bone. This

contrasts strikingly with fiber bone, in which the bundles are coarse, running parallel or interlacing. It is typical of lamellar bone that its fibril bundles are arranged concentrically. In haversian systems, this concentric arrangement is related to the haversian canal. In ground lamellae the concentric arrangement is related to the main marrow cavity, and in spongy bone the arrangement of the lamellae is related grossly to marrow cavities between the trabeculae (fig. 9 *A* and *B*).

The arrangement of the fibrillae in each lamella has been variously described. The question as to whether the fibrils and fibril bundles intertwine has been the main point on which there has been a difference

Fig. 9.—*A*, ground disk of cross-section of human bone as seen under the polarizing microscope. *B*, higher magnification of *A*, showing details of fibrillar structure of three haversian systems and some interstitial lamellae.

in opinion. Koelliker believed that fibrils were straight, and were arranged in closely adjacent straight bundles which did not connect. According to him, these bundles are perforated by numerous canaliculi, but their fibrils do not intertwine. Opposed to this view are the observations of von Ebner and Weidenreich.¹¹ Von Ebner described the fibrils as straight but intertwining, while Weidenreich said that the individual fibrils are twisted spirally and, in addition, intertwine.

11. Weidenreich: *Knochenstudien I. Teil: Ueber den Aufbau und Entwicklung des Knochens und den Charakter des Knochengewebes*, *Ztschr. f. d. ges. Anat.*, part 1; *Ztschr. f. Anat. u. Entwicklungsgesch.* 69:382, 1923.

According to the latter, each fibril bundle in lamellar bone contains only a few fibrils.

The fibril bundles of most lamellae, according to von Ebner and Gebhardt,¹² run spirally, making turns around the haversian canal at angles of approximately 45 degrees, but the degree of the angle may vary from 1 to 90 degrees in the different lamellae of each system, and some of the lamellae may have their fibers parallel to the canal. The general direction of the fibrils changes in each lamella of the haversian system, so that in one lamella the fibril bundles may run clockwise and in the next, counterclockwise, but in some haversian systems a few of the adjacent lamellae may show fibrils running in the same direction

Fig. 10.—Diagrammatic representation of a haversian system, showing the haversian canal, the layers of lamellae with the fibrils running in alternating directions, and the bone cells with their anastomosing canaliculi. After Braus.

(fig. 10). It is believed by most observers that some of the fibrils of each lamella enter the adjacent lamella and in this way bind the lamellae together.

It must be remembered that the haversian lamellae, though disposed about central canals which run longitudinally, are frequently not completely concentrically arranged about the canal, because the diameter and the direction of the lumen of the canal may vary. Some lamellae do not completely encircle the canal because the haversian systems are being altered by reconstructional changes going on in them, which leads

12. Gebhardt: Ueber funktionell wichtige Anordnungsweisen der groeberen und feineren Bauelemente des Wirbeltierknochens, I & II, Arch. f. Entwicklungsmechn. d. Organ. 11:383, 1901; 20:187, 1905.

to irregular resorption within the canal and replacement of the old haversian system by newly deposited lamellae. As a result of resorption, the reconstruction does not produce the identical pattern of the bone but the result is a disordered reconstruction, with numerous irregular haversian systems and parts of systems of all sizes known as breccie. In adult human bone, there are few undisturbed haversian systems, especially as compared with animals. In the bones of the lower jaw and those of the hand and skull, the regularly formed haversian systems are even fewer in number than in the other bones.

The Ground Lamellae.—The compacta or cortex of the tubular bone of man consists, for the greatest part, of haversian systems. On the outer and inner surfaces of the compacta, there is often but not always a system of lamellae running parallel to these surfaces but not related to central blood vessels. These are the ground lamellae. The outer ground lamellae are under the periosteum, by which they are deposited on the haversian columns of the compacta. Since these are formed during the active growth of the bone, it sometimes happens that haversian systems formed later are enclosed in ground lamellae. Inner ground lamellae are present only in the diaphysis of long bones and run in the same general direction as do the outer ground lamellae. They are present in the diaphysis only when there is no spongy bone, that is, when the marrow is in contact with the compacta. These lamellae are deposited from the endosteum. The thickness of the outer and inner ground lamellae varies considerably in different tubular bones and may measure anywhere from 45 to 900 microns. Where the superficial or outer ground lamellae are best developed, some may be present between the haversian systems and may be called interstitial ground lamellae. If such ground lamellae are present, they must not be confused with the interstitial lamellae resulting from the breaking up of haversian systems. The interstitial ground lamellae may be differentiated from the interstitial lamellae that result from the breaking up of haversian systems by the fact that the former contain a few Sharpey fibers, while the latter do not.

The thickness of an individual ground lamella is about like that of an haversian lamella, and the number of ground lamellae varies between 10 and 100. The fine fibrils of the ground lamellae run like those in the haversian lamellae, but the direction of the fibrils may change within the same lamella. The ground lamellae are perforated transversely by Sharpey fibers.

The Interstitial Lamellae.—The interstitial lamellae must not be confused with the haversian lamellae when old haversian systems break. Their formation may be followed by studying cross-sections of compact bone. Existing haversian systems are being constantly resorbed on

the inner or vessel side and replaced by new haversian columns. The junction or line of demarcation of the resorption is represented in section by a shiny and irregular line. If the rate of new bone formation exceeds that of resorption, the old haversian system, that is, the system that is being replaced, splits up, and the fragments of the splintered haversian system fill the spaces between the haversian systems, producing the interstitial lamellae which are also called breccie. The haversian interstitial lamellae form an important supporting mass for the haversian columns of the compacta and nearly always run diagonally. These lamellae are of the same thickness as the haversian lamellae, and the fibrils retain the same appearance and course as existed in the haversian systems from which they formed. In the cortex of adult bone, in addition to the interstitial lamellae, small nests of typical coarse-fibered bone with some bone cells have occasionally been described.

The Cement Lines.—The haversian systems and fragments of haversian systems are separated from each other and from the ground lamellae by sharply defined lines. These were designated as cement lines by von Ebner, the term by which they are now known. These lines are generally quite irregular, though some may be straight. In general, they represent the site of resorption of lamellar bone, and on their surface, facing the haversian canal, new lamellar bone has been deposited. On an average, a cement line is thinner than a lamella, but it may be about as thick as a lamella. The cement lines are non-fibrillar (figs. 11 and 12). Von Ebner found that in the immediate vicinity of the cement lines new formed bone showed no lamellar structure but was made up of fibrils and irregularly distributed cells. This is best seen in the buckled regions of the cement lines, for where the cement lines are straight the lamellae are preserved. Von Ebner noticed that some bone cells lie on the border of the cement lines, which seem to cut them and their processes. He noticed also that the canaliculi of the bone cells in the region of the cement lines do not traverse them but turn away. This was confirmed by Matschinsky.¹³ Schaffer expressed the belief that while most of the canaliculi and bone cells in the region of the cement lines do not traverse them, some actually do and these communicate with the cells of the adjacent haversian systems. Weidenreich believed that anastomoses through the cement lines between the cells of different haversian systems exist, and are important in the transformation and growth of the formed bone. While preparations that my associates and I have made confirm the observations of von

13. Matschinsky: Ueber das normale Wachstum der Roehrenknochen des Menschen Arch. f. mikr. Anat. **39**:151, 1892.

Ebner, we found a few canaliculi which traversed the cement lines, as described by Schaffer.

The cement lines divide the bone into innumerable irregular islands of tissue. The union of these pieces at the cement lines is not as firm as the union of two individual lamellae through the medium of the fibrils and is dependent mainly on the interlocking of the adjacent pieces. In a specimen of macerated bone that had been exposed to the elements for a long time, we found that the lamellae held together very

Fig. 11.—Section through diaphysis of human bone from a case of osteomyelitis. The white lines are the cement lines and illustrate how the cortex is composed of innumerable irregular pieces cemented together. Frozen section stained by Bielschowsky's silver method.

well, but that the haversian systems separated from each other at the cement lines.

In illustration 226 of his "Handbuch der Gewebelehre." Koelliker demonstrated lines found regularly between the periosteal ground lamellae, though they varied in number and thickness. These lines contain no fibrillae of their own; in this respect, they are similar to the cement lines, but differ from them in that Sharpey fibers penetrate them. These lines contain bone cells and canaliculi or may be penetrated by

these structures. They are formed by a deposition of calcareous material in an interfibrillar cement substance and are therefore analogous to cement lines in structure. These lines are formed because bone is deposited underneath the periosteum rhythmically, and between two such lines one can determine the amount of growth that has occurred during a certain period. In the inner ground lamellae of a metacarpal bone, many such lines were found.

Sharpey Fibers.—Sharpey fibers were described under coarse-fibered or primary bone, and they were shown to constitute an important part of this bone. They were described as being present in periosteally formed bone, and being derived from the periosteum. In fine-fibered or lamellar bone, they are few. Sharpey described them as

Fig. 12.—Diagrammatic representation of a cross-section of the shaft of a phalanx of a child, aged 6 years, showing the reconstructional changes going on, and the division of the cortex into innumerable pieces cemented together. After Burkhardt and Petersen.

fibers or fiber bundles which perforate the lamellae, passing through them in a perpendicular or more or less oblique direction. These perforating fibers may be seen with the aid of the microscope in a thin transverse slice of a decalcified cylindric or cranial bone when the ground lamellae are pulled apart. In this way some lamellae will be observed with fibrous processes attached to them which vary in length and usually taper and are pointed at the free extremities but sometimes are abruptly truncated. These fibers have obviously been drawn out from the adjacent lamellae through several of which they must have penetrated. Sometimes, indeed, indications of perforation may be recognized in the part of the section of bone from which the fibers have been pulled out. The processes in question are viewed in profile but they may frequently be seen on the flat surface of detached lamellae, pro-

jecting like nails driven perpendicularly or slantingly through a board, while other lamellae present obvious apertures of considerable size through which perforating fibers have passed. These fibers may also be demonstrated by staining methods. They may be demonstrated in animals like adult guinea-pigs, in which the ground lamellae are well developed, by teasing apart the outer ground lamellae in a thick frozen section.

While some experimenters have been unable to find Sharpey fibers in adult human bone, and this is probably due to the fact that in such bone, ground lamellae may be few or absent. Koelliker and Weidenreich claimed to have demonstrated them in small numbers in subjects up to 60 years of age. In adult bone, Weidenreich and Koelliker found them only in the outer ground lamellae which are derived from the periosteum, and they showed variation in quantity and thickness. According to von Ebner, they appear infrequently in the haversian systems of adult bone. Braus¹⁴ described and illustrated them as occurring in all lamellae, but this is denied by almost all other workers. Weidenreich believed that Sharpey fibers end abruptly at the cement lines. They are estimated as 3 mm. in length in adult human bone. They are believed to prevent the displacement of the ground lamellae. As they pass through the lamellae they sometimes branch, and these branches are directed toward the surface of the bone. They may be quite thick, and nests of these fibers may sometimes occupy a large area in the ground lamellae, and they may have a few bone cells embedded in them. They may then simulate an ossified tendon insertion.

Elastic Fibers.—Von Ebner and Koelliker believed that elastic fibers are found, though seldom, in outer ground lamellae, and according to them some Sharpey fibers are elastic fibers. Von Ebner also described elastic fibers in the innermost lamellae of the haversian system and believed that these fibers were found only in adults. Weidenreich found many elastic fibers in the outer zone of the periosteum, a few in coarse-fibered bone, but none in lamellar bone. On the other hand, Maier¹⁵ and Tafani¹⁶ believed all Sharpey fibers to be elastic fibers. However, the consensus of opinion is that there are few elastic fibers in bone. While some elastic fibers mingle with the Sharpey fibers, others are independent of these fibers, and may accompany the vessels of the cortex.

THE SPONGIOSA

Origin.—Spongy bone makes up most of the mass of the smaller bones like those of the tarsus, carpus, the bodies of the vertebrae and ribs, and the upper and lower ends of tubular bones. While considerable literature exists under the title of spongy bone, most of this literature deals with the question of the influence of the mechanical factors of stress and strain on the architecture of spongy bone, rather than with the question of origin, reconstruction and relation of this bone to the compacta. Furthermore, there has crept into the literature the erroneous statement that all spongy bone is formed from the inner surface of the cortex by a peeling off process, in the course of which cortical haversian

Fig. 13.—Diagrammatic representation of a longitudinal view of a bone, showing both compacta and spongiosa. The cortex on the right shows the outer ground lamellae, with some Sharpey fibers penetrating them. The haversian systems are illustrated, and the longitudinally directed haversian canals are shown. The spongy trabeculae and lamellae are illustrated in the left half of the picture. After Braus.

systems have been widened through resorption by osteoclasts from within the haversian canals. This conception has arisen as a result of the observation, particularly in the upper end of the femur, that some spongy trabeculae are attached at their base to the inside of the compacta. That some spongy trabeculae arise in this way, particularly in the diaphysis, there is no doubt, but in general this conception is wrong.

Structure.—On close inspection, adult spongy bone is found to be composed of slender bars or spicules or thin lamellae of bone which meet and join in a reticular manner, producing an open structure which has been compared to lattice work (figs. 13 and 14). In this way con-

siderable strength is attained without undue weight, and it may usually be observed that the strongest laminae run through the structure in those directions in which the bone naturally has to sustain the greatest pressure. The open spaces or alveoli of the bony network communicate freely. In the fresh state, they contain marrow and blood vessels and give support to these structures.

Due to the variety of the forms of the components of spongy bone, they have been designated by many names. Roux¹⁷ divided the components of spongy bone as follows; (1) tubes (tubuli), (2) hemispherical spaces (pilae), (3) plates (lamellae) and (4) beams (trabeculae). The tubuli ossei are the long spaces in spongy bone enclosed by the thicker trabeculae, and the pilae ossei are curved spaces in spongy

Fig. 14.—A large and more detailed diagrammatic representation of the spongy bone, shown in figure 13. The construction of the trabeculae is plainly seen at the upper surface of the drawing and the surfaces of the lamellae are also seen. The tubuli between the lamellae are represented. The apertures in the lamellae by which the tubuli connect are shown. After Braus.

bone, particularly underneath the articular cartilage and are enclosed by the thinner lamellae. Where the trabeculae or thin lamellae cross each other, a netlike spongy bone is produced. This division of the elements of spongy bone is a rough evaluation, because there are innumerable transition forms and shapes which make a strict terminology impossible. The lamellae and trabeculae of the spongy bone show numerous fine apertures. The marrow spaces which are separated by the trabeculae or lamellae communicate with each other through the apertures. In places the apertures show a regular arrangement, forming pairs of openings placed above each other. The flat surface of the lamella then

17. Roux: Die Entwicklungsmechanik, Vortr. u. Aufs. u. Entwicklungsmech. d. Organ., 1905, nos. 1 to 5.

appears as a strainer. Sometimes larger holes are present, and the face of the lamella appears latticelike.

When the end of the diaphysis of a long bone is examined, it is seen that the cortex becomes thinner from the point where spongy bone appears in considerable amounts. This thinning of the cortex does not necessarily occur uniformly throughout the same horizontal plane of the bone. As was pointed out, the belief is that the cortex thins out because it gives rise to the spongy lamellae, but it must again be emphasized that all the spongy lamellae certainly do not arise from the cortex and that in the epiphyseal ends of the bone the cortex is always thin or inconsequential and the spongy bone is considerable. The appearance

Fig. 15.—Details of structure of a lamella of spongy bone in a ground disk examined with polarized light.

of laminae of bone arising from the cortex is due rather to the spongy lamellae and trabeculae fusing with the cortex.

The spongy trabeculae and lamellae differ from the haversian systems in that only the larger trabeculae contain blood vessels, and compared with the cortex the vessels are few. When trabeculae contain blood vessels, they are surrounded by concentric lamellae. The inner part of a spongy trabecula is composed of small pieces, the breccie, on which layers of lamellar bone are deposited. These breccie consist of small, angular pieces of lamellar bone and are similar to the interstitial lamellae. The lamellae, of which the breccie are comprised, frequently run diagonally to the lamellae on the surface of the trabeculae, and in one trabecula several breccie may be seen, each directed at a different angle. The outer surface of the trabeculae is composed of lamellae which are laid down somewhat concentrically around the marrow spaces.

A few osteoblasts line the trabeculae of adult bone. The trabeculae contain bone cells which anastomose with each other. The fibrillar structure of the trabeculae is no different from that in the lamellar systems. However, the details of the fibrillar arrangement in spongy bone seem not to have been widely investigated. The active cellular bone marrow is supported in the meshes between the spongy bone; and in the diaphysis of long bones of adults, in which the spongy trabeculae are few or entirely absent, the marrow is fatty (fig. 15).

THE RELATION OF FUNCTION TO THE STRUCTURE OF BONE;
WOLFF'S LAW

When the spongy lamellae and trabeculae in the neck of the femur are examined, they are seen to course in archiform effect from one inner wall of the bone to the opposite wall. They cross each other at nearly right angles, and their points of intersection lie nearer that cortex from which the lamellae seem to be separating at the more acute angle. The spongy lamellae and trabeculae as they seem to come off from the cortex make more acute angles the further up they are in the shaft. However, in other bones, like the vertebrae, while the spongy lamellae and trabeculae cross each other to form spaces, there is no particular arrangement of the spongy bone such as occurs in the upper end of the femur.

On the basis of the appearance of the spongy bone in the upper end of the femur, there has been developed the theory of the transformation of bone due to mechanical influences exerted on it. The inner architecture of the spongy bone in this region, that is, the direction and contour of its trabeculae, is supposed to be conditioned by external stresses and strains exerted on the bone. In spite of the large literature and the immense amount of work that has been done on this subject, there is still much difference of opinion as to the proper interpretation of the inner structure of the femur.

The Origin of the Conception of Wolff's Law.—Those who maintain the view that bone is transformed by mechanical influences exerted on it base their beliefs on the observations that the mechanical structure of the normal femur conforms closely to the mathematical proportions of a structure of similar shape and physical properties, the Fairbairn crane, which is designed to resist the action of loads similar in amount and manner of application to those sustained by the human femur. This led to the conclusion that the details of the inner structure of the femur are based on exact mathematical laws, and further, that the form of bone is adapted to its functions.

It is argued that if the external form and inner architecture of a normal bone represent the adaptation to normal function, then alterations in the mechanical demands made on normal bones should be

followed by corresponding changes in both the internal and the external structure. Such changes should produce a deformity, a marked change in contour, or a displacement from the natural normal position. Such changes of contour or displacement from the normal position are regarded as a physiologic adaptation of the structure to pathologic mechanical conditions, and therefore to pathologic function. The doctrine of the functional form of bone, with its corollary of the functional pathogenesis of deformity, has been ably set forth by Julius Wolff, but before him the problem of the mechanics of the inner structure of bone was much discussed. The history of the subject is well reviewed in the monographs of Wolff¹⁸ and Albert¹⁹ and in the more recent American paper by Koch.²⁰ The foundation on which this doctrine rests is the correspondence between the inner structure of the upper end of the femur and the lines of stress in the Fairbairn crane. The analysis of the crane was made by the mathematician, Culmann, who observed that the cancelli of many bones were arranged in forms similar to those which he had computed as the lines of maximum internal stress in a Fairbairn crane having a form which was assumed to approximate that of the upper fourth of the femur. The conclusion was that the cancelli lie along the paths of maximum internal stress and thus transmit a maximum load in the bone with a minimum of material. This observation of Culmann is the mathematical basis of the modern theory of the functional form of bone, and this theory has been criticized on purely mathematical grounds.

The Law.—In 1892, Wolff developed his theory of the relation of the internal structure of bone to function and dealt with the transformation of bone in normal and pathologic cases and discussed in considerable detail the structural changes in bone due to changed mechanical conditions. This work is abundantly illustrated with examples of many rare deformities, taken from collections in the principal museums of Germany. Culmann's mathematical analysis of the lines of stress in the Fairbairn crane and the somewhat analogous direction of the trabeculae in the upper femur are cited by Wolff as mathematical proofs that the architecture of the spongy bone of the neck of the femur follows exact mathematical laws, and that the form and inner structure of bone are determined by the mechanical conditions present.

Recently, Koch published an exhaustive study on the laws of bone architecture. His paper was directed toward bringing definite mathematical proof of the law. He arrived at the same conclusions as Wolff

18. Wolff: *Das Gesetz der Transformation der Knochen*, 1892.

19. Albert: *Einfuehrung in das Studium der Architektur der Roehrenknochen*, Wien., 1900.

20. Koch: *Laws of Bone Architecture*, *Am. J. Anat.* **21**:177, 1917.

did, that the normal external form and internal architecture of the human femur result from an adaptation of form to the normal mechanical demands on, or normal function of, this bone. He stated that the proportions of the femur are everywhere such as to show a definite mathematical relationship between the body weight and the internal structure of the bone; there is a definite relation between the structure and the stress at every point. According to him, spongy bone is homogeneous with compact bone as a structural material and differs from it mechanically only in possessing less strength, which is approximately in proportion to its density as compared with compact bone.

The general law of bone, the adaptation of form to function, holds true mathematically and mechanically in the normal human femur, and therefore, Koch concluded, for all other normal human bones. According to him a foundation is laid for the study and mechanical analysis of the spongy bone entering into the structure of other parts of the skeleton, by the application of the principle that spongy bone and compact bone are homogeneous materials and differ chiefly in strength, approximately in proportion to their densities. The thickness and closeness of spacing of trabeculae in bone vary directly with the intensity of the stresses transmitted by them.

This theory of the functional forms of bone with that of the functional pathogenesis of deformity has been accepted by many surgeons and orthopedists as a working basis in the treatment of deformities, but it has been the subject of so much controversy that much confusion has arisen as to the value of the theory in everyday practice.

Objections to the Law.—Wolff's doctrines of the functional form of bone and the functional pathogenesis of deformity have been vigorously assailed on various grounds by many investigators. Even those who have partly accepted the Wolff-Roux conceptions still feel that in addition to mechanical factors which influence the form and structure of bone, phylogenetic and developmental factors are at work. Even Gebhardt, who was a pupil of Roux, admitted that there are other than mechanical factors influencing the structure of bone. Von Recklinghausen,²¹ although in the main agreeing with the mechanical view, expressed himself as believing that the mechanical views are not sufficient to explain the internal architecture of bone entirely. Friedlaender²² laid most stress on the direction of the vessels in determining the internal architecture of bone. He also stated that much more significance must be attached to the factors of development. Triepel²³

21. Von Recklinghausen: Normale und pathologische Architekturen der Knochen, Deutsche med. Wchnschr. 19:506, 1893.

22. Friedlaender: Beitrag zur Kenntnis der Architektur spongiöser Knochen, Anat. Hefte 23:235, 1904.

23. Triepel: Die Architektur der Knochenspongiosa in neuer Auffassung, Ztschr. f. d. ges. Anat., part 2; Ztschr. f. Konstitutionslehre 8:269, 1922.

would also minimize the importance of the mechanical factors. Petersen²⁴ objected to the theory of Wolff and Roux on the grounds that the calculated direction of the main tension lines of the neck of the femur is not applicable to the bone, since these calculations, obtained from the Fairbairn crane, apply to homogeneous substances with the same elastic properties throughout. But bone is not homogeneous. It is made up of innumerable small pieces which are cemented together and which vary in size and number depending on the internal reconstruction which is always going on. According to Petersen, the determining factor in the structure of bone is functional activity which stimulates bone reconstruction through its effect on the cells, but function does not directly produce the internal structure by exerting a direct mechanical effect on the bone and thus causing the trabeculae and laminae to arrange themselves along certain lines of tension.

Most surgeons have more or less accepted the dicta of Wolff, but most anatomists and embryologists, while agreeing that mechanical factors may influence the inner structure of bone, are of the belief that the phylogenetic and hereditary factors are important, if not most important. It seems to me that this is the most logical point of view. Even if the trabeculae of the head of the femur were arranged in a way to conform with the mathematical principles as applied in the Fairbairn crane, nevertheless this fact could not be explained solely on mechanical grounds because the developmental influence could not be disregarded. In favor of this view is the fact that the trabeculae of all femurs are arranged in practically the same way, irrespective of mechanical influences exerted on them. Also every tissue constructs itself according to a certain pattern, and even in regeneration the original pattern is reconstructed. This is seen in the regeneration of a transplant, as of the thymus, which when placed in the abdominal wall reproduces thymic lobules with cortex and medulla. All tissues have an innate architectural pattern which they produce but which may be influenced by factors like nutrition, function and environment. And so I must agree with those who believe that the mechanical factors, though important, are only secondary in influencing the internal architecture of bone.

SURGERY OF THE ESOPHAGUS*

JAMES H. SAINT, M.D. (DURHAM), M.R.C.S., L.R.C.P.

Fellow in Surgery, The Mayo Foundation

ROCHESTER, MINN.

Surgical procedures have been employed for the relief of several pathologic conditions in the esophagus, the most common being the impaction of foreign bodies, cardiospasm, benign cicatricial stricture, carcinoma and diverticula. Impacted foreign bodies are now much less commonly dealt with by surgical means because of the easier and less dangerous method, in the hands of experts, of extraction through the esophagoscope, while surgical procedures have been almost eliminated from the treatment for cardiospasm. In this article the last three conditions, essentially, are considered.

Until within the past fifty years the esophagus received scant attention from the surgeon in spite of the well recognized pathologic conditions for which, theoretically, surgical procedures might well have been indicated. This is all the more striking when one remembers that the ancient Hindoos operated on the bladder for stone, and that Herophilus of the Alexandrian School used the knife boldly on such internal organs as the liver and spleen. For many years the only operative procedure attempted on the esophagus was esophagotomy of its cervical part. This was followed by the more complicated and drastic plastic operations and resections. The latter have so far been attended by a depressing mortality, so that some of the most stout-hearted surgeons often prefer to leave the anatomic relations of the viscus undisturbed rather than bring about almost certain death by surgical intervention. It is well known that when Billroth began to popularize his gastric operations he did so at the cost of many lives; yet nothing is more gratifying than the results of surgical methods in this sphere today. Moynihan¹ and Balfour² recently each reported a large series of

* Submitted for publication, Nov. 12, 1928.

* An abridgment of the thesis awarded the Heath Scholarship of the University of Durham, 1928. The experimental work was done at the Division of Experimental Surgery and Pathology, The Mayo Foundation, under the direction of Dr. F. C. Mann. It is realized that this article falls far short of being a comprehensive survey of the subject, and for more complete works the reader is referred to such books on thoracic surgery as those of Ferdinand Sauerbruch (*Die Chirurgie der Brustorgane*, Berlin, Julius Springer, 1925, vol. 2) and Howard Lilienthal (*Thoracic Surgery*, Philadelphia, W. B. Saunders Company, 1925, vol. 1), or to the recent monograph of Victor von Hacker and G. Lotheissen (*Chirurgie der Speiseröhre*, *Neue Deutsche Chir.* 34:569, 1926).

1. Moynihan, Berkeley: *Two Lectures on Gastric and Duodenal Ulcer: A Record of Ten Years' Experience*, Bristol, John Wright & Sons, 1923, 48 pp.

2. Balfour, D. C.: *Fundamental Principles in Surgery of the Stomach and Duodenum: Report of 400 Cases*, *Surg. Gynec. Obst.* 42:167, 1926.

operations on the stomach with a mortality ranging from 1 to 2 per cent. Thus, by dint of perseverance and improvement in technic from time to time, that which was once a great risk has been converted into a safe every-day occurrence. This is not so in regard to esophageal surgery. The results of operative work in this sphere have been disappointing on the whole, in spite of modern advances in asepsis and technic. Esophagotomy can be performed fairly safely and diverticula can be removed without much risk, but carcinoma still claims its victims, operation in most cases serving only to hasten death. Still, some of those skilled in thoracic surgery, such as Torek, Meyer, Eggers and Lilienthal, have hopes that the time is not far distant when the surgeon will be able to wage war successfully against it. In his Hunterian Lecture, Abel³ took the same optimistic view.

Two facts stand out prominently in a consideration of surgery of the esophagus: (1) its comparatively recent history and (2) its slow and unsatisfactory progress. The undoubted cause of the first fact seems to be the relative inaccessibility of the esophagus, the viscus being deeply seated throughout its entire course. At first it took courage to make the deep dissection of the neck necessary for its exposure and surgical treatment. When this had been achieved it was probably thought impossible to expose the thoracic portion because of its intimate relations with such viscera as the pleura, lungs and aorta, injury to any of which must always be regarded with grave concern. For some time attempts were not made to lay bare the esophagus in its thoracic bed. Then came the development of the technic of posterior mediastinotomy whereby the esophagus could be reached without entrance to the pleural cavity. Later still, the invention of the differential-pressure chamber, by overcoming the well recognized occurrence of fatal postoperative pneumothorax, opened the road to the esophagus through the pleural cavity. Today it may be said that the surgeon's initial difficulty with regard to the esophagus, namely, that of overcoming its inaccessibility, has been solved. At least thus far has surgery of the esophagus progressed.

Although, as I have mentioned, the less severe operations of esophagotomy and extirpation of diverticula can usually be successfully performed, one seeks for explanations of why the more extensive operations, with a few exceptions, have been failures. Here one must remember that the final aim of the surgeon is to overcome carcinoma. Resection is therefore essential, and it is in the treatment of the esophagus after resection has been carried out that most of the difficulties which are at present preventing the progress of surgery in this sphere have arisen and still remain.

3. Abel, A. L.: The Treatment of Cancer of the Oesophagus, *Brit. J. Surg.* 14:131, 1926.

Theoretically, the operation of resection with end-to-end anastomosis is feasible; however, several factors exist to add to its risk and difficulty. At the present time, carcinoma of the esophagus is not diagnosed early enough. In most cases it would seem that this is due to the delay on the part of the patient in consulting a surgeon, but some patients with a very short history on examination are found to be suffering from extensive carcinoma. In either case, by the time the diagnosis is made the growth has invaded the esophageal wall to such an extent that the amount of the viscus to be removed in order to extirpate the carcinoma widely enough is much greater than that which would allow the cut ends to be brought together and sutured.

Assuming that a carcinoma is of such dimensions that when extirpated the cut ends of the esophagus can be brought together without undue tension, what other difficulties are there to overcome? The esophagus differs from the bowel in that it does not possess a serous covering. The significance of this is apparent. When the bowel is sutured, the peritoneum, in response to the traumatic irritation imposed on it, throws out lymph which coagulates, thereby sealing the line of suture. The surgeon does not get natural help of this sort from the esophagus, and consequently the safety of the suture of this viscus is greatly impaired. It is the general opinion that apart from the absence of help from serosa, the wall of the esophagus forms poor material for suture, both submucous and muscular coats being easily cut through. In this connection, Miller and Andrus found that if the lower third of a freshly removed human esophagus is divided and then joined by two layers of fine silk sutures grasping the submucosa, the artificial juncture withstands the pressure of a column of water 6 feet (182.9 cm.) high without the escape of either gas or fluid. From this investigation it is clear that the esophageal wall has the required strength, but the important point to be remembered is that in the living body its strength is dependent entirely on a sufficient blood supply.

Unfortunately, the esophagus is poorly supplied with blood although this is derived from several arteries, the aorta, inferior thyroids, subclavians, left inferior phrenic and left gastric. The great danger in end-to-end anastomosis of the esophagus is constriction of the blood vessels by the sutures, which is only too often the cause of necrosis with perforation of its wall and consequent leakage of its contents, resulting in fatal infection of the mediastinum or cellular planes of the neck. The loosening of the esophagus in its bed previous to resection, by necessitating severance of some of its blood vessels, will have already considerably diminished the nutrition of its cut ends, sometimes to such a degree that necrosis and gangrene ensue apart from any further diminution by constriction with sutures.

The outer coat of the esophagus consists of connective tissue continuous with that of the structures surrounding it. Carcinoma will usually be found to have invaded this and to have fixed the viscus. The loosening of the growth involves an opening of the cellular planes of the neck or the connective tissues of the mediastinum, and a grave risk is thereby incurred, because of the danger of ensuing cellulitis or mediastinitis which may take place in spite of the most careful aseptic precautions. This risk is always present, even when the esophagus is only loosened in its bed; however, if the lumen is opened, the risk increases considerably because of the highly infective nature of the esophageal secretion.

Coincident with the danger of mediastinitis is that of infection of the pleura, and the remarks concerning the former apply with equal force to the latter.

If the carcinoma extends through the esophageal wall the vagi are always involved and usually cannot be separated; they must be cut if resection is to be carried out. Although severance of these nerves does not always produce any apparent detrimental results, it is possible, and even probable, as Meyer pointed out, that interference with them plays a great part in bringing about the state of shock which has so many times proved fatal.

Lastly, the presence of the diaphragm has added considerably to the technical difficulties of operations on the lower end of the esophagus from the standpoint of resection of this part of the viscus and its substitution by stomach or intestine.

The chief reasons for the late inception of surgery of the esophagus, its relatively slow progress and its lack of attendant success can be summarized as follows:

1. The inaccessibility of the viscus; this applies particularly to the thoracic portion where its surgical approach is intimately bound up with previously developed operative procedures on the pleural cavity.

2. The absence of a serous coat in its cervical and thoracic parts.

3. A poor blood supply, interference with which often results in necrosis with tearing of sutures and extravasation of infective mucous secretion.

4. The danger of postoperative infection, cervical cellulitis, mediastinitis, pleurisy and empyema.

5. The probable danger of great shock resulting from interference with the vagi.

6. The presence of the diaphragm.

DEVELOPMENT OF ESOPHAGEAL SURGERY

The literature on surgery of the esophagus shows the great ingenuity that has been displayed by surgeons in their attempt to effect cures of the various pathologic conditions.

The earliest operations were essentially those of cervical esophagotomy, the simplest operation possible on the esophagus performed in its most accessible part for the extraction of foreign bodies. Thus, the first surgical measures were in the nature of emergency operations. Goursauld,⁴ in 1738, appears to have been the first surgeon to perform this operation. It was not found mentioned again until nearly a century afterward when Rolland,⁵ in 1819, performed it successfully. In 1833, Arnott,⁶ of the Middlesex Hospital, was the first Englishman to perform esophagotomy. The patient died fifty-six hours after the operation. Arnott remarked that he could not find any record of the operation having been done in England up to the time of his own attempt. In 1858, Cock⁷ said: "I can find but very few cases recorded in which the pharynx and esophagus have been opened for the purpose of extracting a foreign body." He himself successfully performed esophagotomy on a man who had swallowed a tooth plate.

In 1868, Cheever⁸ reported two successful cases and reviewed the literature on esophagotomy up to that time. He reviewed twenty-three other cases; however, the issue had not been successful in all. His list of surgeons contained the well known names of Syme and Nélaton, the latter being of the opinion that the operation was one of the gravest and most difficult in surgery.

The usual method employed for exposing the cervical esophagus and removing a foreign body was as follows: A left lateral incision was made along the inner border of the sternomastoid muscle from the level of the upper margin of the thyroid cartilage downward for about 10 cm., with incision through skin, platysma and deep fascia. If the anterior jugular vein was encountered, it was cut between ligatures. The omohyoid muscle was then either cut or retracted and the hyoid depressor muscles retracted medially while the sternomastoid was drawn laterally. The esophagus was found between the thyroid gland medially and the carotid sheath laterally and was incised longitudinally over the foreign body as far posteriorly as possible so as to lessen the risk of injury to the recurrent laryngeal nerve. The foreign body was then extracted and the esophageal wound closed with interrupted sutures or left open, the former practice being the more usual.

4. Goursauld, quoted by Cheever: *Two Cases of Esophagotomy for the Removal of Foreign Bodies*, ed. 2, Boston, J. Campbell, 1868.

5. Rolland, quoted by Cheever: *Two Cases of Esophagotomy for the Removal of Foreign Bodies*, ed. 2, Boston, J. Campbell, 1868.

7. Cock, Edward: *A Case of Pharyngotomy for the Extraction of a Foreign Body*, with Some Remarks. *Guy's Hosp. Rep.* 4:217, 1858.

8. Cheever, D. W.: *Two cases of Esophagotomy for the Removal of Foreign Bodies*, with Some Remarks, ed. 2, Boston, J. Campbell, 1868.

There are a few points with regard to this operation which appeared in the literature at that time and which are worthy of note. There was a controversy as to the relative merits of a median and a lateral incision. The advocates of the former, among whom was Nélaton, preferred the median line with splitting of the thyroid cartilage so as to avoid injury to the recurrent laryngeal nerves. Those who recommended the lateral incision declared that with care these nerves could be avoided easily and that the exposure they obtained was superior to that obtained by their opponents. Whether or not a swelling appeared in the side of the neck after the impaction of a foreign body in the esophagus was given considerable attention. Several surgeons went so far as to say that the absence of swelling was a contraindication to operation. Again the advisability of ensuring drainage in case of leakage of secretion through the wound in the esophageal wall was well recognized.

At this time an attempt had not been made to expose the thoracic portion of the esophagus, and the only hope of extracting a foreign body impacted in that portion lay in being able to reach it from above through cervical esophagotomy or from below through gastrotomy. In 1886, because of this Richardson⁹ made some observations on the accessibility of foreign bodies fixed in this part of the esophagus. In experiments on cadavers he found that a finger introduced into the esophagus through a low incision in the neck could easily be brought into contact with a finger inserted upward through the stomach. As a result, he asserted that there was not a part of the esophagus which might not be reached with the finger either by gastrotomy below or by esophagotomy above. He also showed the easy distensibility of the cardia which allowed the introduction of two fingers up through it simultaneously, a distinct advantage to the operator attempting to free an impacted foreign body. These observations were of considerable practical value at that time. Since then the advent of the esophagoscope has dispensed almost entirely with the necessity of the extraction of impacted foreign bodies by the external route, because the danger entailed by the latter procedure is usually regarded as greater than that by the former.

As time went on it was only natural that surgeons should begin to devise ways and means of laying bare the thoracic part of the esophagus. It was natural, too, that an extrapleural route should be chosen because of the well recognized danger of pneumothorax resulting from opening of the pleural cavity.

⁹ Richardson, M. H.: A Case of Gastrotomy, Digital Exploration of the Esophagus and Removal of Plate of Teeth: Recovery, *Boston M. & S. J.* **115**:567, 1886; The Possibility of Operations on the Esophagus Through the Stomach as Shown by Dissections, *Lancet* **2**:707, 1887.

In 1888, Nasiloff¹⁰ working on the cadaver, resected from three to six ribs posteriorly, and through a vertical incision close to the vertebral column pushed forward the pleura, stripped it off the esophagus and thus exposed this structure extrapleurally. This is the first record in the literature of posterior mediastinotomy: the operation was a distinct advance not only in surgery of the esophagus but in thoracic surgery.

Quénu and Hartmann,¹¹ in 1891, and Potârcă,¹² in 1894, demonstrated subperiosteal resection of portions of the second to the sixth ribs on the cadaver, entering the posterior mediastinum and exposing the esophagus. They hoped that by this method of approach the resection of carcinoma of the esophagus would be feasible.

In 1895, Bryant¹³ devised another method of approach to the mediastinal portion of the esophagus. Instead of a straight vertical incision like that of Nasiloff,¹⁰ Quénu and Hartmann,¹¹ and Potârcă,¹² he made a quadrilateral flap with its base at the spinal column. The flap included all tissues down to the ribs and when it was raised from the underlying structures it was reflected medially. Three ribs were exposed and the middle one was resected for a length equal to that of the flap. The ribs above and below were divided only and turned medially with the intervening intercostal structures, forming a flap with its hinge near the vertebral column. After this the operation was carried on after the manner of Nasiloff and the esophagus exposed. Bryant demonstrated his method on the cadaver.

Rehn,¹⁴ in 1898, was apparently the first to employ a modification of Bryant's operation on the living subject. He made a large muscle flap with its base extending from the third to the ninth spinous process and then resected several ribs (an osteomuscular flap as devised by Bryant was not used). In the first operation he wounded the pleura; pneumothorax developed and the patient died six weeks after operation. In the second operation, the exposure of the carcinoma was satisfactorily carried out but the lesion was definitely inoperable. Suppuration of the wound and death on the sixth day followed. The esophagus was approached from the right side in both cases.

Llobet,¹⁵ in 1900, was the first to perform Nasilloff's operation on a human being, the case being one of benign stricture of the esophagus. Following a left paravertebral vertical incision and resection of several ribs, he pushed forward the pleura and exposed the esophagus without difficulty. There were two strictures which he incised longitudinally and then inserted a soft sound through the nose down into the stomach so as to model the lumen of the esophagus. The patient died eight days after operation. Purulent empyema was found at necropsy and was attributed to infection of the pleural cavity by the regurgitated gastric contents. Llobet called attention to the fact that he could have reached the esophagus in this position (just below the aortic arch) much better from the right side. He considered the operation feasible.

In 1901, Enderlen¹⁶ using the flap method, operated on a patient for the removal of a tooth plate in the thoracic portion of the esophagus. He extracted the plate successfully but in doing so injured the edges of the esophageal wound so severely that he decided not to suture but to drain. The patient was nourished through a previously made gastrostomy opening and although he was not well enough to be dismissed from observation until nine months after the operation, he recovered. Enderlen advised that the approach to the thoracic portion of the esophagus above the bifurcation of the trachea be made from the left side.

Henle,¹⁷ like Enderlen, performed posterior mediastinotomy for the removal of a foreign body in the esophagus. The patient died nine days after operation. In 1903, Faure¹⁸ and Tuffier¹⁹ exposed the esophagus by the posterior mediastinal route, but the patients died. Tuffier mentioned the transpleural route for exposure of the esophagus but believed that the danger from pneumothorax and pleural infection was almost too great.

By this time posterior mediastinotomy as an approach to the thoracic portion of the esophagus had become a recognized surgical procedure. There thus remain two approaches to be considered: the anterior mediastinal and the transpleural. The former is mentioned merely to be condemned. In Cairo in 1897, Milton²⁰ split the manubrium and body

of the sternum longitudinally in the median line and was able to pull the two halves about 6 cm. apart. This operation was undertaken for the removal of tuberculous lymph nodes, and it is easy to see that this procedure or any of its modifications as a means of reaching the esophagus extrapleurally is decidedly impracticable and well nigh impossible, because of the numerous important structures which lie in the way. Apart from this, the exposure of the esophagus, once it was obtained, would not be nearly so good as by the other two routes.

An Italian surgeon, Biondie,²¹ in 1895, was the first to attempt to explore the esophagus by the transpleural route; he used the dog as his subject. He employed a paravertebral incision followed by resection of two or three ribs. The pleura was incised, the pleural cavity opened, and the esophagus exposed by incision of the parietal pleura.

The opening of the pleural cavity for the intrathoracic operation on the esophagus or any other of the thoracic viscera was not put on a safe basis, however, until the invention of the differential-pressure chamber by Sauerbruch²² and the positive-pressure apparatus by Brauer and Petersen²³ in 1904. These inventions, by preventing collapse of the lung during operation and pneumothorax afterward, gave a great impetus to intrathoracic surgery, including that of the esophagus. They have been replaced largely by the simple method of intratracheal insufflation introduced by Meltzer and Auer²⁴ in 1909.

Now that the dangers of opening the pleural cavity have been overcome to such an extent that the surgeon need not hesitate to operate in it, there remains only the question of the type of incision to employ in order to get the required exposure. Dobromysslav, for example, used the flap method with subperiosteal resection of the underlying ribs. Sauerbruch introduced the simple intercostal incision of skin, muscles and pleura. This he found eminently suitable for experimental work on dogs, and it is still the most commonly used for that purpose. The usual procedure for opening the pleural cavity in man now includes either the division of ribs or their resection. Torek, in his famous case, cut down to the ribs through a curved incision, the anterior part of which was over the seventh intercostal space while the posterior part turned vertically upward near the vertebral column. He then divided the seventh, sixth and fifth ribs just lateral to their tubercles, and the

pleural incision ran parallel to that in the skin. By retraction excellent exposure of the middle part of the pleural cavity was obtained and the esophagus easily reached. The level of the incision was planned according to the part to be explored.

The exposure of the posterior mediastinum for the laying bare of the thoracic portion of the esophagus extrapleurally has also received attention as time has gone on, and Lilienthal's²⁵ recent method, a modification of that employed by Torek, gives excellent exposure. His incision starts 20 or 22.5 cm. from the spine at whatever level he chooses and runs backward along a rib to the edge of the longitudinal spinal muscles and then curves upward parallel to the spine for four or five intercostal spaces. The rib over which the incision is made is resected subperiosteally, and the rib below and two or three above are divided just lateral to their tubercles. The usual care is taken in the ligation of intercostal vessels and the separation of the pleura from the periosteum of the ribs and intercostal muscles. By the introduction and spreading of a rib retractor, these ribs, which have been divided, are easily "shingled," one on top of the other, and thus exposure is obtained.

Grégoire's²⁶ extrapleural and extraperitoneal method of exposing the lower thoracic and cardiac segments of the esophagus is interesting and might well be mentioned. A U-shaped incision with unequal limbs is made on the left side of the thorax. It starts behind at the level of the eighth rib near the spine and runs vertically downward over the necks of the ribs until it reaches the twelfth where it curves forward along that rib for about 10 cm.; then it turns upward in the posterior axillary line to the level of the eighth rib. A musculocutaneous flap is raised, the twelfth rib resected, the eleventh sectioned at each end of its exposed part and the tenth cut only through its neck. The arteries in the corresponding intercostal spaces are ligated and cut and a large osteomuscular flap can then be raised, exposing the pleura and below this the diaphragm. The pleura is pushed forward off the vertebral column, aorta, esophagus and diaphragm. After the diaphragm is bared, it is split close to the neck of the twelfth rib near the esophageal orifice, and here the left inferior phrenic artery must be ligated before it is cut as its ends are likely to retract. After being split the diaphragm is retracted with the pleura and good exposure of the lower end of the esophagus is obtained.

For operations on the esophagus by the posterior mediastinal route, the side by which the better exposure is obtained still remains a matter

25. Lilienthal, Howard: Posterior Mediastinotomy, *Arch. Surg.* 6:274 (Jan.) 1923.

26. Grégoire, Raymond: Voie d'accès sur le segment cardio-œsophage permettant d'éviter la plèvre et le péritoine. (Voie thoraco-abdominale extra-séreuse), *J. de chir.* 21:673, 1923.

of the choice of the individual surgeon; most are agreed that the right side is better for operations in the region of the hilum and that the lower part of the thoracic portion of the esophagus is better approached from the left.

From the foregoing brief outline of the development of surgery of the esophagus, it can be seen that the viscus has become accessible throughout the whole length of the course. In the thorax two routes are available, the extrapleural and the transpleural. The abdominal part of the esophagus can be exposed through either the abdominal or the thoracic route.

LESIONS OF THE ESOPHAGUS

All lesions in the esophagus have a tendency to cause narrowing of the lumen, thus producing obstruction with its attendant symptoms. The esophagus, like any of the other hollow viscera in the body, may be obstructed by causes: (1) in the lumen, such as foreign bodies and tumors (polypi); (2) in the wall itself, such as cardiospasm, congenital stricture or stricture resulting chiefly from fibrosis in injury, inflammation or new growths—tumors, apart from fibrosis, may lead to narrowing—and (3) outside the wall, such as tumors, diverticula, aneurysms, enlarged lymph nodes and abscesses.

Treatment, whether or not it is surgical, is always directed toward relief from the obstruction. With regard to impacted foreign bodies, it is noticed that their removal has passed largely from the domain of surgery since the advent of the esophagoscope. Should operation be the only available means of relief, however, it would consist in exposure of the esophagus at the site of impaction and longitudinal incision through the wall over the foreign body followed by extraction with as little resultant trauma as possible. The edges of the esophageal wound would then be brought together, usually with two rows of sutures, the second inverting the first. Drainage must be provided for. Should the impacted foreign body be situated in the cardiac or lower thoracic part of the esophagus, it might be possible to extract it through a gastrotomy wound by digital manipulation and so avoid the risk entailed of opening the esophagus.

As mentioned, operation has been almost eliminated from the treatment for cardiospasm, and its place has been taken by the more conservative treatment of dilatation.

The stricture resulting from fibrosis following injury or inflammation (benign cicatricial stricture), when believed to be impermeable, has been treated by the plastic formation of an artificial esophagus which circumvents the stricture and reestablishes continuity between the mouth and stomach. In order that the surgical treatment of a carcinomatous stricture may be successful, resection of the growth itself is essential. Although subsequent end-to-end anastomosis may be attempted, it is

more usual to bridge the gap caused by the resection by some plastic procedure. Hence two series of operations for the relief of stricture have been attempted: esophagoplastic operation alone and resection with or without a plastic operation.

ESOPHAGOPLASTIC OPERATIONS

The types of plastic operations devised for the relief of benign cicatricial strictures which are believed to be impermeable, having as their object the formation of an artificial esophagus, have been many and various, and no tissue or viscus that would seem suitable has been neglected. Thus, skin, fascia, stomach and large and small intestines have all been used. Before the introduction of these operations, patients were usually subjected to gastrostomy, and there surgical treatment ended. Gastrostomy as a temporary measure is helpful, but as a permanent one it has many drawbacks and may become a veritable nuisance, particularly for a working man. The patient's food must always be specially prepared; the skin around the gastrostomy opening often becomes ulcerated and difficult to keep clean, and, what is even more exasperating to the patient, nothing has been done which will restore to him the joy of taking food by mouth and the power of deglutition for which he seems to crave and without which life seems to be intolerable. In spite of this unfortunate state to which gastrostomy may lead, many surgeons regard it with favor and publish statements to the effect that their patients are well satisfied with the results. Another fact which must be given just consideration is the youth of most of the patients suffering from benign stricture of the esophagus (many of them are actually children); to provide them only with a gastrostomy opening will limit their enjoyment of social intercourse and activity, and probably seriously jeopardize their chances of success in life. The realization of these drawbacks to gastrostomy was the factor which led to the introduction of esophagoplasty.

It may take months to complete the plastic operations, and the futility, as well as the lack of justification, of performing them in cases of carcinomatous stricture without primary resection of the growth itself has long been recognized. I shall describe the various types of esophagoplastic operations.

Skin.—In 1894, H. Bircher attempted extrathoracic esophagoplasty for carcinomatous stricture, using the skin of the anterior wall of the thorax and the neck. The first step was to make two vertical parallel incisions about from 7 to 8 cm. apart, slightly to the left of the median line and extending from the submaxillary region to the margin of the rib. The edges of the strip of skin were turned forward and brought together in the median line by interrupted sutures so that a tube lined by epidermis was formed. The edges of the skin of the incision on

both sides were undermined for 1 or 2 cm., pulled together and sutured over the tube of skin already formed. About six weeks later a gastrostomy opening was made and its edges connected with those of the lower opening of the tube of skin. Nine days later fluid nourishment was poured through the tube from above and it entered the stomach without trouble. Three days later the patient died of pulmonary embolism. At necropsy it was found that the sutures of the tube had given way in some places. The second patient died from pneumonia, and Bircher found that the anterior part of the tube of skin had separated for about 4 cm. and that from this opening the lumina of both stomach and tube could easily be reached. Bircher had intended to make a juncture between the upper end of the tube with the cervical part of the esophagus. He stated that although fluid food passed down the artificial esophagus with ease, he did not believe that solid food would, owing to the absence of peristalsis in the tube. Although Bircher's attempts to form a new esophagus were made in 1894, they were not published until 1907, by E. Bircher.²⁷ This procedure and its modifications, which seem to be the safest of all the methods devised for esophagoplasty, curiously enough seem to have been forsaken for a long time through the introduction of other much longer and more dangerous procedures, and have found favor again only during the last few years.

Payr,²⁸ in 1917, seems to have been the first to complete successfully Bircher's technic; the patient was a young man, aged 20.

In 1917, Esser²⁹ devised an ingenious method of forming a tube of skin to act as a new esophagus. He considered that in the formation of a tube according to Bircher's method there was likely to be too much tension on the skin and he found a method of avoiding this factor. He first performed a Witzel operation for gastrostomy. Then he made a transverse incision about 4 cm. long through the skin of the anterior wall of the thorax midway between the jugular notch and the gastrostomy opening slightly to the left of the sternum. After entrance to the subcutaneous tissues through the incision with a suitable instrument, he undermined the skin upward and outward to the level of the thyroid gland and downward to the gastrostomy opening. The thickest instrument was from 2.5 to 3 cm. in diameter. He then proceeded to line the tunnel with Thiersch skin grafts, so that when these had taken he

27. Bircher, Eugen: Ein Beitrag zur plastischen Bildung eines neuen Oesophagus, *Zentralbl. f. chir.* **34**:1479, 1907.

had a tube lined by skin and formed in such a manner as to avoid tension. The technic of applying the grafts to the inside of the subcutaneous tunnel is interesting. He split a rubber drainage tube longitudinally and painted it with albumin (white of egg); when this was dry, he laid on it the Thiersch grafts, wound side outward, and turned the edges of the grafts into the longitudinal slit. The adhesion of the Thiersch grafts to the tube by the medium of the egg-white enabled the tube to be introduced into the tunnel with the grafts in position. Two graft-covered tubes were inserted, one into the upper part of the tunnel, the other into the lower part. Their approximated ends were connected by a core made of sterile wood. After ten days, the rubber tubes were removed and the upper and lower parts of the skin tube united by suture. In his first case, Esser had considerable difficulty in uniting the cervical portion of the esophagus with the upper end of the tube of skin because of the high position of the stricture and the consequent short length of the oral end of the esophagus. He managed, however, by closing the defect with skin flaps. He effected the juncture of the gastrostomy opening and the lower end of the tube of skin by constructing a sac from the abdominal wall to surround both orifices. The sac was made in the same way as the Bircher tube of skin. By this method a valvelike arrangement was made whereby he hoped to prevent the regurgitation of gastric contents (with their deleterious effects on the Thiersch grafts) into the skin tube, for the sac would have to become filled first and in filling would compress the anterior wall of the lower end of the skin tube against the posterior wall and so close the orifice. His first case was successful and at the time of writing he had begun a second case but had completed only the formation of the tube of skin by his Thiersch graft method.

In 1921, Fonio³⁰ suggested that the lower end of the tube of skin be joined directly to the wall of the stomach, the mucosa being sutured to the lower edge of the tube of skin followed by serous sutures inverting the wall of the stomach, as in a Senn gastrostomy. The soft tissues, then the skin, would be brought together and sutured over the anastomosis of the stomach and tube of skin.

Realizing the advantage of a seroserosus suture, Galpern,³¹ in 1925, sought to remedy this defect in the lower end of the skin tube by the use of omentum. He first made a transverse incision in the skin about 8 cm. long, midway between the xiphoid and the umbilicus, and undermined the skin above it, making a subcutaneous pocket from 5 to 6 cm. long. In this he placed omentum, which was extracted from

30. Fonio, A.: Ein Fall von antethorakalen Oesophagoplastik, Schweiz. med. Wchnschr. 51:865, 1921.

31. Galpern, E. J.: Eine neue Methode der Oesophagoplastik, Zentralbl. f. Chir. 52:182, 1925.

the abdomen. A week later, he made a tube of skin according to the method of Bircher, the lower edge being formed by the transverse incision, so that the lower 4 or 5 cm. was surrounded with omentum which had grown together with the subcutaneous tissues. In this way Galpern provided a serosal covering for the lower part of the skin tube, to which the stomach might then be united. He experimented on rabbits and dogs. In the former, all experiments were failures because the skin covering the pocket became mummified and unsuitable for the formation of a skin tube. By his experiments on dogs he was able to convince himself that the omentum grows together with the subcutaneous tissue and will take part in an anastomosis as serosa. He expressed the belief that heterogeneous omentum procured during laparotomy, for example, can be used with greater facility and with equally good results. His experiments were not completed when he made his report.

In 1922, von Engelbrecht³² reported a case of a girl, aged 15, on whom he performed anterior esophagoplasty for impermeable stricture. He successfully completed the artificial esophagus, although he had some trouble with the formation of fistula at the juncture of the skin tube and the esophagus above the gastrostomy opening and skin tube below.

In 1925, Rovsing³³ described a method which appeared to be a modification of that introduced by Bircher with which Rovsing appears to have been unfamiliar. Juncture of the lower end of the skin tube and the gastrostomy opening is effected in a manner similar to that in which Esser made the sac, except that the amount of skin used is just sufficient to form a tube continuous with the lower end of the skin tube above and surrounding the gastrostomy orifice below. An interesting modification which Rovsing introduced lay in his treatment of the aboral end of the esophagus after its division in the neck. Instead of closing it, which is the usual practice, he brought it out through a small incision in the left supraclavicular fossa, fixed it to the skin with silk and drained it with a tight rubber drain. In this way he avoided the possibility of mediastinitis which might ensue from the inefficient closure of the aboral end or from the giving way of the closing sutures because of tension resulting from secretion accumulating above the stricture. At this time he reported two successful cases, and in 1926, this number had increased to four, with a fifth which was incomplete.³⁴ Two of the patients were boys aged 5 and 9 years.

In 1926, Braizew³⁵ completed esophagoplasty on a girl, aged 12, by means of skin, although the procedure occupied nearly a year and necessitated many operations. His technic differed from the technics described in that he avoided the juncture of the skin tube with the gastrostomy opening by making a second opening in the stomach near the cardia. This allowed the temporary use of the first opening for feeding purposes and also reduced the length of the skin tube. The second opening was made by drawing up a cone of stomach into the abdominal wound and surrounding it with crossed muscle strips from the rectus abdominis, thus forming a sphincter. The functional result was good, the patient being able to swallow any kind of food.

Anterior Wall of the Stomach.—In 1901, Depage³⁶ by devising a new method of gastrostomy, paved the way for the later real esophagoplastic operations. He used a vertical flap from the anterior wall of the stomach with its base upward and close to the lesser curvature. By closing the stomach with a continuous suture and continuing this on to the upturned flap, he converted the latter into a tube which he found could be drawn upward through a parietal tunnel almost to the xiphoid process. In 1903,³⁷ he reported having used the method in six cases with satisfactory functional results.

In 1911, Hirsch³⁸ employed the same method but with the intention of replacing the lower part of the esophagus by the tube formed by the suturing of the edges of the flap. He made the longitudinal axis of the flap parallel to that of the stomach with the base toward the fundus, in this way ensuring a good blood supply from the branches of the left gastric and short gastric arteries. The lower end of the tube was fixed to the peritoneum to avoid kinking, and the tube itself was brought up onto the thorax subcutaneously. Jankovskis³⁹ quoted E. Hesse as having performed the Hirsch operation four times with two successful results. This is the only instance noted in the literature of the use of this operation on man. Jankovskis also pointed out that its disadvantage lies in the fact that the stomach considerably diminishes in size in cases of impermeable esophageal stricture.

Greater Curvature of the Stomach.—In 1905, Beck⁴⁰ started to improve gastrostomy by the formation of a plastic tube from the greater curvature of the stomach, with its base to the left, thus ensuring a good blood supply by means of the left gastro-epiploic artery. He cut a flap, and, by a continuation of the suture which closed the stomach on to the edges of the flap, brought them together and so formed a tube. Starting first with a small flap, he gradually extended the operation until most of the greater curvature was included in the flap. He then found that the tube was of such length that it could be brought upward on the surface of the thorax far enough to be united to the cervical portion of the esophagus. By measurements on the cadaver, he came to the conclusion that the operation was feasible on the human being. His experiments, which were briefly recorded in a journal of limited distribution, were not spread abroad in the general medical literature, and, consequently, the credit of having devised this form of esophagoplasty has mostly gone to Jianu,⁴¹ who, in 1912, apparently in ignorance of Beck's work, published similar experiments on dogs and on the cadaver and advised the use of the method for benign stricture in the human subject. After the formation of the tube, its base is sutured to the peritoneum in the upper part of the abdominal wound. A vertical median line incision is made in the skin of the thorax and the edges undermined. The tube is then drawn upward, laid in this subcutaneous path and the edges of skin sutured together over it. The edges of the end of the tube are sutured to those of a transverse incision at the upper end of the vertical one. Later, anastomosis can be made between the oral end of the transversely cut cervical portion of the esophagus and the upper end of the tube made from the greater curvatures.

Röpke,⁴² in 1921, was the first to use the Beck-Jianu type of esophagoplasty in operating on the human being. He performed the operation on a man with carcinoma of the esophagus, but did not do a resection. Instead of making a subcutaneous pathway for the artificial esophagus as did Jianu,⁴¹ he tunneled below the pectoral muscles. The gastric contents did not regurgitate. The case was successful apart from the fact that the carcinoma was not resected.

In 1913, Meyer⁴³ published a report of three cases in which the Beck-Jianu method of operation was successful. The first case was

complicated by gangrene of the seromuscular coat of the uppermost extremity of the new esophagus. He believed this was due to the constricting action of the through-and-through sutures on the vessels, and formed the opinion that the mucosa alone should be sutured to the borders of the skin wound. In this case, Meyer had followed Röpke's method of leading the new esophagus through a subpectoral tunnel. Submuscular suppuration and perichondritis ensued. In his other two cases, he used Huelte's wire-stitching instrument for the closure of the longitudinal incision in the stomach; it has the great advantage that the stomach is not even opened. Meyer preferred the subcutaneous rather than the subpectoral placing of the Beck-Jianu tube because local infection is easier to deal with, and there is less risk of its spreading to the ribs or sternum. In another publication, Meyer⁴⁴ advised the intrathoracic use of the Beck-Jianu tube to replace the lower portion of an esophagus that had been resected for carcinoma.

In 1914, Jianu⁴⁵ reported the cases of the first two patients treated by this method. Both were cases of benign stricture, and the results were successful. He stated that it was feasible to perform the operation not only on a normal stomach, but also on one which might be adherent to the abdominal wall, as after gastrostomy.

In 1913, Enderlen and Hotz⁴⁶ reported their experimental work on esophagoplasty. They stated that their efforts to substitute a loop of small bowel or a Beck-Jianu tube for the esophagus uniformly resulted in gangrene, and that the mobilization of the proximal portion of the cervical esophagus resulted in failure because of necrosis of its end.

In 1919, Nicolaysen⁴⁷ published the report of an interesting case. A few years previously the patient had undergone a Wullstein and Roux⁴⁸ type of operation for esophageal stricture. The jejunal loop had necrosed, the operation thus being a failure. Nicolaysen then operated by the Beck-Jianu method, completing the new esophagus by a tube of skin. Complete success rewarded his efforts.

In 1922, Lotheissen⁴⁹ reported four cases in which successful operations were performed by this method. In two of them the cervical portion of the esophagus was united directly with the Beck-Jianu tube, while in the remaining two this juncture had to be effected by the interposition of a tube of skin about 10 cm. long. In one of the latter cases, regurgitation of gastric contents caused erosion of the skin tube so that many minor plastic operations had to be performed for repair, the outcome finally being successful.

In 1926, Grigorjev⁵⁰ in a plastic operation, made a tube from the greater curvature of the stomach, constructed in such a manner as to open into the stomach near the pylorus, in this respect differing from the Beck-Jianu tube. It was brought up to the clavicle without tension. The functional result was poor: fluids would not pass into the stomach through the tube, and if introduced through a stomach tube, they regurgitated into the new esophagus. This was thought to be due to the resistance of the pyloric sphincter; a plastic operation was performed on this structure, but there was no improvement in function. The patient died after four months. Grigorjev considered this operation unsuitable and recommended the Wullstein-Roux type of esophagoplasty.

Whole Stomach (Antiperistaltic).—In 1913, von Fink⁵¹ devised a method of operating on a patient who had a carcinoma of the cardia and lower end of the esophagus. At operation he found the cardia forming a stiff funnel and adherent to the liver. He mobilized the remainder of the stomach and first part of the duodenum, cut through the juncture of the first and second parts of the duodenum and closed the distal end. He then brought up the stomach over the left margin of the ribs onto the anterior thoracic wall subcutaneously, although the extent to which he did this was naturally limited by the fixation of the cardia. The opening of the duodenum reached to about the level of the nipple. Posterior gastro-enterostomy was then performed. Later, the cervical portion of the esophagus was united to the duodenal opening. After a few days, blood-stained fluid flowed from the abdominal wound. The fluid increased in amount, and the patient became weaker and died. By this operation von Fink established in his own mind the usefulness of the stomach and duodenum as material for esophagoplasty.

Whole Stomach (Isoperistaltic).—In 1920, Kirschner⁵² introduced a new method of esophagoplasty, in which, like von Fink,⁵¹ he used the whole stomach. After ligating and dividing the left gastric, left gastro-epiploic and short gastric arteries, he mobilized the whole stomach by cutting through the gastrocolic and gastrohepatic ligaments. He then cut through the stomach about 4 cm. below the cardia and, after making an anastomosis between the cardiac stump and the jejunum, he drew up the stomach subcutaneously, cardiac end first, in front of the wall of the chest. He thus arranged the stomach in an isoperistaltic way, because he feared the effect of antiperistalsis which might cause trouble in the von Fink type of operation. Later, the cervical portion of the esophagus was to be anastomosed to the cardiac end of the stomach. Kirschner reported one case in which the operation was completed with a successful result, which, however, took twenty-seven months to attain, the chief difficulty being the contraction of the cervical esophagostomy opening, which required many minor plastic operations. His second patient lived only a month, and died from abscess of the lung. At necropsy an ulcer was found in the displaced stomach at the level of the third rib; it had perforated into the pectoralis major muscle.

In 1921, Kümmell⁵³ performed esophagoplasty, using Kirschner's method in three cases of impermeable stenosis due to cardiospasm, benign stricture and inoperable carcinoma, respectively. All three patients died soon after the operation. In two of them, Kümmell did not anastomose the cardiac end of the esophagus with the small intestine. In each of them, the accumulation of secretion above the closing ligature resulted in rupture with peritonitis. At necropsy, there were no signs of impairment of nutrition of the wall of the stomach in any of the cases.

In regard to the mobilization of the stomach, the work of Miller and Andrus,⁵⁴ in 1923, is of importance. They found that in nineteen dogs in which the left gastric and short gastric arteries, as well as the anastomotic branches from the phrenic arteries near the cardia were ligated, only one showed any alteration in the viability of the stomach; a definite necrosis of a limited portion of the fundus took place. On the other hand, if one goes a step further and divides the left gastro-epiploic artery (as Kirschner did), one finds that in dogs at least two thirds of the stomachs so treated show an area of necrosis on the

fundus from 3 to 4 cm. in diameter, involving the entire thickness of the wall and resulting in acute perforating ulcer. Such a lesion was found in Kirschner's⁵² second case. In view of their experience, Miller and Andrus considered Kirschner's method of mobilizing the stomach a risky procedure.

In 1926, Wajgiel,⁵⁵ working on dogs and cadavers, made injections into the stomachs after the ligation of the left gastric, short gastric and left gastro-epiploic arteries. He found that the fundus of a stomach, the blood supply of which had been treated in this manner, was not filled with the injection mass. This corroborates the observations of Miller and Andrus.

Jejunum.—Wullstein,⁵⁶ in 1904, was the first to utilize the jejunum for esophagoplastic work; he performed his experiments on the cadaver. He resected about 15 cm. of jejunum taken from the intestine a short distance (about 30 cm.) below the duodenojejunal flexure. After the reestablishment of the continuity of the bowel by end-to-end or lateral anastomosis, he pulled up the resected jejunal loop with its attached mesentery through the transverse mesocolon and greater omentum and anastomosed the aboral end to the anterior surface of the stomach. The oral end of the loop was then drawn up onto the anterior thoracic wall and sutured to the thoracic musculature along the left border of the sternum; over the loop of intestine so fixed he sutured the skin flap made with its base to the left prior to the opening of the peritoneal cavity. The anterior circumference of the end of the jejunal loop was sutured to the skin laid over it. The next step was to make a tube of skin in a similar manner to that of Bircher and to join it below to the upper end of the jejunum and above to the oral end of the divided cervical portion of the esophagus.

In 1907, Roux⁵⁷ performed his famous successful operation of esophagojejunogastrostomy on a child suffering from intractable benign esophageal stricture. In reality this was a modification of Wullstein's method. His results with gastrostomy in benign stricture had been poor, and he decided to attempt to form a new esophagus with the aid of the small intestine. He took the jejunum because of the regularities of the arteries supplying it and the ease with which they are recognized. He first resected a loop of the upper portion of the jejunum of a length calculated to reach almost to the pharynx. Toward its oral end he ligated and cut the vascular stems of the arcades and then divided the mesentery.

55. Wajgiel, Eugenjusz: Experimentelle Untersuchungen über die Gefäßversorgung des Magens insbesondere mit Rücksicht auf die Operation der vollständigen Oesophagoplastik nach Kirschner, abstr. Zentralorg. f. d. ges. Chir. **36**:34, 1926-1927.

56. Wullstein (footnote 48, first reference).

57. Roux (footnote 48, second reference).

At its aboral end, he conserved the mesentery containing one or more arterial stems, and thus obtained a length of intestine supplied with blood through its mesenteric pedicle. Then followed the reestablishment of the continuity of the intestine by a button for intestinal anastomosis. The resected loop was drawn up in front of the transverse colon and the aboral end implanted in the stomach close to the lesser curvature, care being taken not to compress the transverse colon. By means of Richelot forceps, Roux undermined the skin of the thorax just to the left of the sternum as far upward as the manubrium, where they came out through a transverse incision. By opening the forceps and giving them a to-and-fro movement, he made a tunnel through which the jejunum was easily drawn, and the circumference of the end of the loop was sutured to the edges of the wound in the skin. The peritoneum was closed. After the wounds had healed, the subcutaneous intestinal loop could be seen to contract actively at intervals. Roux was later going to join the cervical portion of the esophagus to the upper end of the jejunal loop and so complete that which he set out to do.

Thus, to Roux belongs the credit of proving the feasibility of making a new esophagus from the intestine in human beings. It infused new enthusiasm into the minds of many who had hitherto believed such surgical success to be impossible, and this was reflected in the increased number of case reports of attempted esophagoplasty which began to appear in the literature. Judging from the literature, of all types of esophagoplasty the Wullstein-Roux method has proved the most popular. The juncture of the cervical portion of the esophagus with the jejunal loop sometimes is direct as devised by Roux, and sometimes by skin esophagoplasty according to Wullstein.

In 1908, Herzen⁵⁸ performed a Roux operation on a patient with carcinoma. Death followed sixteen days afterward. Herzen was not satisfied with Roux's technic and sought to change it somewhat, the chief modification being the passing of the jejunal loop through the transverse mesocolon and gastrocolic omentum so as to shorten it and to avoid the possibility of compression of the transverse colon. Later, he completed the operation in two cases with success. The first was that of a man with carcinoma of the esophagus, who was shown at the Seventh Russian Surgical Congress, at which time he enjoyed good health. The other was that of a girl, aged 20, who had stricture which resulted from swallowing sulphuric acid. Herzen mentioned that in this case intestinal peristalsis showed itself in the jejunal loop after each new mouthful of food. His modification of shortening the path of the jejunal loop by passing it through slits in the transverse mesocolon and

58. Herzen, P.: Eine Modification der Rouxischen Oesophagojejunogastrostomie, *Zentralbl. f. Chir.* 35:219, 1908.

gastrocolic omentum had already been suggested by Wullstein in 1904. In 1908, Wullstein⁵⁹ drew attention to the similarity of his method to that of Bircher and Roux.

In 1911, Lexer⁶⁰ performed a Roux operation for carcinoma of the esophagus. Gangrene of the subcutaneous loop of intestine ensued. He performed the Wullstein operation in another case with success. Lexer, watching this case, made the important observation that the absence of peristalsis in the section containing the skin tube of the artificial esophagus did not have an adverse effect on the ingestion of food. Thus, Bircher's doubts as to the ability of such an esophagus to allow the passage of solid food were settled. It was a most interesting observation from the physiologic standpoint as it proved that the esophagus itself plays a small part in deglutition, and that the descent of the food bolus is due to the impetus given to it by the contraction of the pharyngeal muscles.

Since this time many surgeons have reported one or more cases in which this type of operation was performed with varying degrees of success. The list is so large that only references will be given: Frangenheim,⁶¹ Heyrovsky,⁶² Blauel,⁶³ Rehn,⁶⁴ Sýring,⁶⁵ Axhausen,⁶⁶ Bornhaupt,⁶⁷ Hirschmann,⁶⁸ Fromme,⁶⁹ von Hacker,⁷⁰ Ranzi,⁷¹ Peter-

Colon (Isoperistaltic).—In 1911, Kelling,⁸⁸ impressed by Lexer's⁶⁰ successful case which had just been reported, decided to attempt a similar operation, and chose as his patient a man, aged 45 with an ulcerating esophageal carcinoma. When the abdomen was opened he noticed the shortness of the mesentery of the small intestine as compared to that of the transverse colon, and therefore decided to try the suitability of this part of the large intestine for esophagoplasty. He resected a large piece of the transverse colon, reestablished the continuity by end-to-end anastomosis, closed the right end of the resected portion and anastomosed its left aboral end to the anterior surface of

the stomach near the fundus. The mesentery of the resected portion of the colon was preserved completely only at its left end and thus contained the left colic artery. A Kader type of gastrostomy was performed. The colon was drawn up onto the anterior thoracic wall, the skin of which was incised and undermined to receive it. The colon was laid in the subcutaneous channel and the skin sutured over it. The blind end of the colon was sutured to the upper part of the skin wound. The patient was nourished through the gastrostomy opening for a few days, and then the blind end of the colon was opened and the mucous membrane sutured to the skin. About a month after the first operation, the esophagus was brought out of the neck, and an attempt was made to bridge the gap between the esophageal fistula and the upper end of the colon. The patient collapsed and died when everything seemed to be going well.

Colon (Antiperistaltic).—In 1911 also, Vulliet⁸⁹ devised an operation similar to that of Kelling, but performed it only on the cadaver. The point of difference between the two methods is that Vulliet preserved the mesenteric pedicle at the right (oral) end of the resected intestine, and he anastomosed this end to the stomach, drawing the left (aboral) end up onto the chest. Thus, his arrangement of the resected portion of the colon was antiperistaltic. This did not worry Vulliet because of the observations of Lexer and Frangenheim which seemed to show that the peristalsis in such an excluded loop of intestine was hardly worth consideration.

The reports in the literature on esophagoplastic operations in which an excluded portion of the transverse colon was used have been few, and in those in which full reports are given the Kelling type of operation has been most commonly performed.

Von Hacker,⁹⁰ Fonio,⁹⁰ Lundblad,⁹¹ Ritter⁹² and Lotheissen⁴⁹ have all reported cases.

In 1923, Roith⁹³ devised a new one-stage method of esophagoplasty, using a part of the transverse colon and the cecum and ascending colon. He performed his operation on a man on whom gastrostomy had been performed for stricture of the esophagus. At the end of seventeen

days the patient was well enough to go home; the gastrostomy opening had closed. The patient fared well for three years, and then died of an intercurrent disease. Roith's procedure was as follows:

A large abdominal incision was made from the xiphoid process downward, at first vertically, then diagonally through the right rectus, as a good exposure is necessary. The cecum was loosened, the parietal peritoneum cut lateral to the ascending colon and this portion of intestine freed. The ileum near the ileocecal valve was cut through and both ends closed blindly. Transverse section was made of the middle of the transverse colon with blind closure of both ends, ileocolostomy by lateral anastomosis between the closed ends of the proximal ileum and the distal colon, and anastomosis between the aboral end of the excluded colon and the upper part of the anterior wall of the stomach. The cecal end of the colon was drawn up into the anterior thoracic wall subcutaneously to the neighborhood of the left clavicle where, after exposure of the cervical portion of the esophagus, anastomosis was made laterally by interrupted sutures to the cecum. This completed the one-stage esophagoplasty.

Comment.—Up to the end of 1921, Lotheissen⁴⁹ reviewed eighty-nine cases reported in the literature in which esophagoplasty for the relief of benign stricture had been performed by various methods. Forty-five of these operations were complete and 44 were incomplete. By the end of 1923, this number had been increased to 101 (von Hacker⁷⁰ and Lotheissen), with 50 complete and 51 incomplete. In 1926, Denk⁸⁵ added 19 complete cases from the literature to this list. He omitted, however, the cases of Sebestýen⁸⁴ (6 complete and 4 incomplete), Flechtenmacher⁸² (1 incomplete) and Jankovskis³⁹ (4 complete and 1 incomplete), and since he wrote, the reports of Perthes,⁹⁴ Braizew³⁵ and Albrecht⁸⁷ have appeared, each of whom completed 1 case, of Grigorjev⁵⁰ and Pokotilo⁸⁶ whose cases were incomplete, and of Rovsing⁹⁵ (2 complete and 1 incomplete). These additions (a total of 24 cases) are the result of a search in the literature up to the end of 1927, and make the total number of recorded esophagoplastic operations for benign stricture 144, of which 84 have been completed, with 60 incomplete. Death, sometimes from intercurrent diseases but usually resulting from the operative procedures, has been the most common reason for incompleteness: in the list compiled by von Hacker and Lotheissen it accounted for 25 of the incomplete cases, while in my additional 9 incomplete cases reviewed from the literature there were 5 deaths. The total mortality amounts to 20.8 per cent.

95. Rovsing (footnotes 33 and 34).

The case reports show an overwhelming preponderance of jejunoplasty by means of skin over the other types of jejunoplasty. This is particularly noticeable in the most recent cases: for example, in my collection of 24 cases. Only those of Rovsing,⁵³ Braizew⁵⁴ and Grigorjev⁵⁰ were done by other methods, leaving 18 which were performed by the Wullstein-Roux-Herzen type of operation.

It can be seen from the foregoing account of the esophagoplastic procedures that in a case of impermeable stricture the surgeon has the choice of several types of operation. They may be divided into two groups: those in which an abdominal viscus is used (beyond simple gastrostomy) and those in which the entire antethoracic esophagus is made from the skin of the wall of the chest.

The first group suffers from two disadvantages which are common to all types of operation belonging to it, whether the stomach, jejunum or colon is used. They are the risks of gangrene of the antethoracically transposed viscus due to insufficiency of, or interference with, its blood supply, and peritonitis. Although the latter is usually successfully guarded against by the adoption of present-day methods of surgical technic, the former must always remain a much more serious risk since it is dependent on several factors.

The disadvantages of jejunoesophagoplasty as performed by Roux are at once apparent. The loop of jejunum was so long that its blood supply could not be otherwise than poor. Moreover, by bringing up the loop in front of the transverse colon, the mesenteric pedicle was twisted, and there was risk of compression of the colon by it. Herzen corrected these faults by his modification of bringing up the jejunal loop through an incision in the mesocolon, thereby passing it behind the transverse colon. Hirschmann⁵⁶ suggested another improvement by making the skin tube so that its lower end is at the level of the xiphoid process, thus further shortening the length of the jejunal loop necessary for this operation, ensuring a much better blood supply and preventing the blind saclike dilatations near its juncture with the stomach which have sometimes given cause for resection.

Kirschner's⁵² method has the advantage that, with the exception of the anastomosis of the cervical portion of the esophagus with the stomach, the whole operation is done in one stage. It presents two difficulties, however: the anastomosis of the cardiac end of the esophagus (or the remaining cardiac part of the stomach) with the small intestine and the transposition under the skin of such a large viscus. The work of Miller and Andrus,⁵⁴ and later that of Wajgiel,⁵⁵ and the occurrence of a perforating gastric ulcer in one of Kirschner's cases would seem to indicate that the blood supply of such a mobilized

⁵⁶ Hirschmann, Carl: *Komplikationen bei der totalen Oesophagoplastik, Ihre Beseitigung und Verhütung; zugleich ein Beitrag zur Verwendung der "Epithaleinlage,"* Arch. f. klin. Chir. **122**:553, 1922.

stomach may, in a fair percentage of cases, prove to be so inadequate as to prevent the adoption of this type of esophagoplasty in preference to others.

Next to jejuno-esophagoplasty the method of Beck and Jianu has won most favor. Its disadvantages lie in the long suture line and in the production of acid and pepsin by means of the mucous membrane, the corrosive effect of which may seriously compromise healing. Most cases in which this method was used seem to have been successful in spite of the doubt cast on it by the experiments of Enderlen and Hotz, who found gangrene of the tube formed from the stomach in every case. Meyer and Lotheissen both regard this method as the best type of esophagoplasty.

In the Kelling and Vulliet type of operation, it is thought that the risk of peritonitis is considerable because of the virulence of the organisms usually found in this part of the bowel. There is also to be considered the difficulty of bringing up the colon subcutaneously, owing to its bulk. In these cases there is a tendency for food to collect and remain for some time on the lower part of the transposed loop before it passes into the stomach; this may affect the comfort of the patient.

In this group all the acids of the viscera are capable of peristaltic movement and may be transposed in either an isoperistaltic or an anti-peristaltic way. If in the former, then peristalsis, although usually it does not greatly help the functional results, at least is not detrimental to it. When the viscus is placed in an antiperistaltic manner, one would expect that peristalsis would adversely affect the function of the new esophagus. Under these circumstances, however, it behaves in such a paradoxical way that it seems impossible to foretell the result. Sýring arranged his jejunal loop antiperistaltically, and peristalsis, by causing a copious regurgitation of gastric juice, led to complete failure of the operation. On the other hand, Jankovskis performed a similar type of operation, and had no trouble whatsoever from this source.

In the second group fall the method of skin esophagoplasty of Bircher⁹⁷ and its modifications. These have a great advantage over the methods in the first group in that the only intra-abdominal operation necessary is simple gastrostomy, which in many cases has already been done as a palliative measure some time before it was decided to undertake the formation of an antethoracic esophagus, thus rendering any subsequent intra-abdominal procedure increasingly difficult because of adhesions. It has been realized that peristaltic action in an artificial esophagus is unnecessary; the cases of Torek⁹⁷ and of Eggers⁹⁸ are

97. Torek, F.: The First Successful Case of Resection of the Thoracic Portion of the Oesophagus for Carcinoma, *Surg. Gynec. Obst.* **16**:614, 1913.

98. Eggers, Carl: Resection of the Thoracic Portion of the Esophagus for Carcinoma: Report of a Successful Case, *Arch. Surg.* **10**:361 (Jan.) 1925.

proof of this. The formation of the tube of skin in males is likely to be difficult because of the tightness of the anterior thoracic skin, but tension can usually be relieved by means of suitably placed incisions. Judging from the literature, the least difficult and most successful part of any total antethoracic esophagoplasty is the formation of the skin tube.

Common to both groups are the difficulties that accompany the esophagostomy. There is often a marked tendency to stenosis. This should be overcome by the passage of bougies or by small plastic operations before anastomosis with the upper end of the skin tube is attempted. Some authors advise the direct union of the esophagus with the upper edge of the skin tube; others, that it should be united first with the skin of the neck and afterward the two orifices enclosed by a small tube of skin. The flow of saliva from the esophagostomy opening generally retards healing at this point. Some of the earlier workers were content to make only partial division of the esophagus and to unite the cut edges to the skin. This practice has been superseded by transection, on the grounds that by the former method food gained access to the culdesac above the stricture, resulting in stagnation and infection.

At the lower end of the skin tube the corrosive effect of the regurgitated gastric juice may retard healing at its juncture with a transposed abdominal viscus or the gastrostomy, causing fistula and necessitating many minor plastic operations.

Although many successful attempts have been made to form an artificial esophagus by antethoracic esophagoplasty, the surgeon who undertakes the operation should realize that he accepts a grave responsibility. It takes months to complete the procedure, the mortality is not low and success is far from being assured even if death does not occur. The avoidance of the necessity of the operation depends largely on a proper understanding of the term impermeable.

It has been known for many years that a swallowed silk thread will often worm its way through a stricture through which the smallest bougie cannot hope to penetrate. This fact formed the basis of von Hacker's⁹⁹ successful "sondierung ohne Ende" method of treating benign stricture. The lower end of the silk thread is drawn out of a gastrostomy opening, while a rubber tube is attached to the upper end, which is drawn downward through the stricture by pulling on the lower end of the thread. The upper end of the rubber tube is in turn attached to one of greater diameter, and this is next drawn down through

99. Von Hacker: Zur Behandlung tiefsitzender Narbenstricturen der Speiseröhre durch Sondierung ohne Ende nach temporärer Gastrostomie Oesophagostomie mit Bemerkungen über die Verwendung ausgezogener Drains zur Drainage ohne Ende. Wien. klin. Wchnschr. 7:455 and 480, 1894.

the stricture. By a continuation of this process, rubber tubes of gradually increasing diameters can be used to dilate the stricture to the required size. This method was modified by Dunham¹⁰⁰ who made use of metal sounds instead of rubber tubes. Mixer¹⁰¹ went a step further and introduced a modification of Dunham's technic which abolished the necessity of gastrostomy. He conceived the idea of using a silk thread which had passed through the stomach into the intestine, far enough to admit of its being drawn taut, as a guide for passing dilating sounds through the stricture. H. S. Plummer¹⁰² recognized the value of this method and introduced it into the Mayo Clinic where it is now carried on successfully by Vinson.¹⁰³ Many of Vinson's patients who have had gastrostomy performed for "impermeable" stricture, and others who, according to the roentgenologist, had complete occlusion, have swallowed a thread and it passed through the stricture, in spite of the fact that even the smallest sound failed to pass. He has not failed to dilate successfully in any such case. Reports in the literature show that many of these plastic procedures have been undertaken simply because the smallest bougies could not be passed through the stricture, and in view of the foregoing facts it would seem that many patients have been submitted unjustifiably to operations of long duration and considerable risk. No doubt there are rare cases in which anatomic impermeability occurs, and the lumen is completely occluded or at any rate obliterated to such an extent that all efforts to get a silk thread to pass through the stricture are of no avail. On the other hand, it should be recognized that in almost all severe cases the impermeability is only clinical and not anatomic, and can be satisfactorily treated by the well tried and successful method which has been described.

If a stricture finally becomes anatomically impermeable, it means that the stricture must have passed through the stage of clinical impermeability, at which time it was either neglected or wrong, or insufficient treatment was instituted. During its passage from clinical to anatomic impermeability, gastrostomy must have been performed; otherwise, the patient would have died from starvation. Hence, all patients who have an anatomically impermeable, benign, cicatricial stricture have been submitted also to gastrostomy. The question of further surgical intervention by the formation of an artificial esophagus now arises and

102. Plummer, H. S.: *The Value of a Silk Thread as a Guide in Esophageal Technic*, *Surg. Gynec. Obst.* **10**:519, 1910.

103. Vinson, P. P.: *Personal communication to the author.*

is dependent on the efficiency of the gastrostomy. Should the patient be satisfied with this, nothing further need be done. On the other hand, should the gastrostomy prove inefficient and bring unbearable discomfort in its train, then antethoracic esophagoplasty is justifiable, provided that the risks and uncertainty of success are pointed out to the patient and he is willing to allow the surgeon to operate on the chance of success, which, if achieved, will allow him to take his place once again as a normal person.

Here a plea is made for the prevention of the progression of benign cicatricial stricture to either clinical or anatomic impermeability. So often the histories of patients suffering with this condition are stories of neglect, on the part either of the patient or of one or more physicians. Rutherford Morison's aphorism "Once a stricture, always a stricture" is as true of the esophagus as it is of the urethra, and if such patients were told this and were impressed with the likelihood that the stricture might become impermeable if not treated properly, there is no doubt that their negligence, often the outcome of ignorance, would be largely prevented. Thus, regular systematic dilatation could be undertaken and started shortly after the onset of the affliction. In this way cases of impermeable stricture would be reduced considerably or might be abolished altogether, although some authors hold the opinion that in rare cases the progression of a stricture to impermeability apparently cannot be prevented.

RESECTION WITH OR WITHOUT ACCOMPANYING PLASTIC OPERATIONS

The goal for which surgery is ever striving in esophageal work is successful resection for carcinoma. The difficulties in obtaining successful results have been discussed. They are as yet far from being surmounted with any degree of regularity. Judging from the literature, it would seem that every method which ingenuity can invent has been practiced for the purpose of reestablishing the continuity of the esophagus after resection either in the dog (the animal most frequently used for experimental esophageal surgery) or in man.

Cervical Portion.—The earliest reports concerning resection of the cervical portion of the esophagus are those of Billroth¹⁰⁴ and Czerny.¹⁰⁵

Billroth,¹⁰⁴ in 1871, was the first to turn his attention to resection of the esophagus, with extirpation of carcinoma as his ultimate object. He performed the operations on dogs. After exposing the esophagus, he freed it from the surrounding connective tissue, resected about 1.5 cm.

104. Billroth, T.: Ueber die Resection des Oesophagus, Arch. f. klin. Chir. 13:65, 1871.

105. Czerny, quoted by von Hacker: Arch. f. klin. Chir. 87:257, 1908.

and sutured the cut ends together. The first dog died in five days from a phlegmon of the neck. The second dog fared better; a fistula formed which discharged for several months but finally healed, and the dog lived in health until it was killed.

In 1877, Czerny,¹⁰⁶ one of Billroth's pupils, was the first to extirpate successfully the cervical part of the esophagus for carcinoma in a human being. He made the usual incision along the anterior border of the left sternomastoid and removed the portion of the esophagus from just below the pharynx to below the thyroid gland, thus being well clear of the tumor above and below; in all, about 6 cm. of the esophagus was removed. The distal end of the esophagus was stitched into the lower part of the skin wound, and the patient was fed by tube through the esophagostomy opening. She died fifteen months after the operation from recurrence.

In 1884, Mikulicz¹⁰⁶ went a step further; he followed resection of a cervical esophageal carcinoma with plastic repair of the fistula resulting from the operation. Four months after the first operation, he cut out the fistula with its surrounding skin, and on each side cut a small flap of skin with its base medially. He turned these flaps inward so that the epidermis was inside, and sutured their edges together. The skin lateral to the flaps was drawn together over them by means of silver wire sutures. The wound healed by first intention, and after ten days the patient was able to swallow solid food. Death from recurrence occurred sixteen months after resection.

Mikulicz' plastic operation was an afterthought, and von Hacker,¹⁰⁷ in 1886 and 1887, appears to have been the first to attempt partial and complete removal of the circumference of the cervical portion of the esophagus with the express intention of following the operation immediately with the replacement of the esophageal defect by the skin of the neck. He first experimented on dogs and performed two types of operation, either leaving posteriorly a longitudinal strip of esophageal wall from 1 to 2 cm. in width or removing the whole circumference. In the first type he reconstructed the posterior esophageal wall by lateral flaps of skin. In the second, instead of employing a vertical incision in the skin, he made two horizontal incisions distant from one another slightly more than the length of the portion of the esophagus to be resected, thus forming a bridge of skin which when undermined was freely movable. After resection, the bridge of skin was dropped back into the wound, and its upper and lower edges sutured to the posterior edges of the corresponding esophageal orifices, thus reconstructing the

106. Mikulicz, J.: Ein Fall von Resection des carcinomatösen Oesophagus mit plastischem Ersatz des excidirten Stückes, *Prag. med. Wchnschr.* **11**:93, 1886.

107. Von Hacker, Victor: Zur Pharyngo- und Oesophagoplastik, *Zentralbl. f. Chir.* **18**:121, 1891.

posterior wall of the esophagus. In both types he undertook to reconstruct the anterior wall of the esophagus by the formation of two rectangular flaps of skin, the outer edges of which he turned medially and sutured together in the median line. The skin lateral to the flaps was undermined enough to permit of its being drawn together over the inverted flaps of skin and sutured over them (Bircher²⁷ employed the same principle on a larger scale for his antethoracic skin tube).

The opportunity to carry out the operation on a human subject presently came to von Hacker.¹⁰⁷ He formed two rectangular flaps of skin before performing the resection, but as he left none of the esophageal wall behind, he brought the flaps together, sutured them in the median line and stitched their upper and lower angles to the circumference of the posterior esophageal wall. Before the second step of completing the skin tube by the formation of the anterior wall from the flaps of skin, the patient died.

In 1898, Garrè¹⁰⁸ published a report of three cases of carcinoma in the cervical portion of the esophagus, in which he performed resection. One patient lived for about a year after the operation. In another case the larynx was extirpated also and its mucous membrane used successfully for esophagoplasty, being sutured to the pharynx above and the esophagus below, thus forming a new posterior esophageal wall.

In 1908, von Hacker¹⁰⁹ reported the work done up to that time on resection of the cervical portion of the esophagus. Altogether, he reviewed twenty-five cases from the literature. In almost all of them plastic repair had been attempted, but was completed in only a few cases. The most interesting fact to be gleaned from his report is that, except for his own second case, Czerny's patient lived the longest after operation (fifteen months). That this patient thirty-one years previously had been the first to undergo resection of the cervical portion of the esophagus indicates clearly the lack of progress in this type of surgery up to this time. In 1908, von Hacker described his second case, in which, after preliminary gastrostomy, resection of nearly all the cervical portion of the esophagus was undertaken, together with the total extirpation of the larynx and the trachea down to a short distance above the jugular notch. The trachea was sutured to the skin, and the first stage of the plastic operation was done by suturing a right-sided rectangular flap of skin into the esophageal defect. Later he performed the second stage, completing the formation of the tube of skin by turning inward the two rectangular flaps of skin, joining them together in the median line

108. Garrè, C.: Ueber Oesophagus-Resection und Oesophagoplastik, Arch. f. klin. Chir. 57:719, 1898.

109. Von Hacker, Victor: Ueber Resection und Plastik am Halsabschnitt der Speiseröhre, insbesondere beim Carcinom, Arch. f. klin. Chir. 87:257, 1908.

and covering them with two lateral flaps, one longer than the other, so that the suture line was to one side and not in the median line. The third stage consisted in completing the juncture between the pharynx and skin tube. After fourteen months the patient had gained 19 Kg. (40 pounds), and on examination at the end of sixteen months after the operation was in good health.

In 1911, Lane¹¹⁰ introduced the single skin-flap method for plastic repair after resection of the cervical portion of the esophagus. He cut a horizontal flap 5 cm. deep and 12.5 cm. long with its base to the left of the neck. The flap was then reflected toward its base. The upper part of the esophagus was exposed and the carcinoma removed with a margin of uninvolved esophageal wall. The removed segment of esophagus was then replaced by folding the flap in the form of a tube in the longitudinal axis of the esophagus. The upper margin was sutured to the pharynx and the lower to the divided esophagus. After a sufficient interval for firm union of the skin esophagus to the portions of the normal esophagus at the lines of section, the attachment of the skin flap by its base to the skin of the neck was divided, and any lateral aperture which remained in the skin esophagus was closed. The danger of necrosis of the skin flap is in direct proportion to its length. The patient progressed for some time, but death occurred seven months after the operation from perforation of the carotid artery due to recurrence of the growth. Two years later, Ach¹¹¹ attempted an operation similar to that of Lane. His patient died soon afterward.

In 1913, Gluck,¹¹² commenting on the 48 per cent operative mortality among the twenty-five cases reviewed in the literature by von Hacker¹⁰⁹ in 1908, reported that he had operated in forty-seven such cases with only five deaths.

The experiments which have led to the attempted replacement of a resected portion of the esophagus by fascia had their origin in those of König,¹¹³ in 1911, who successfully reinforced esophageal suture lines by a flap of cervical fascia and platysma. Kostenko and Rubaschew¹¹⁴ went a step further and succeeded in replacing small oval resected por-

tions of the cervical part of the esophagus. Razzaboni,¹¹⁵ using the peritoneum and sheath of the rectus abdominis, and Neuhoof,¹¹⁶ with autogenous fascia lata, did similar work.

Allen,¹¹⁷ in 1923, was the first to attempt the experimental replacement of the whole circumference of the resected esophagus by autogenous fascia lata. His efforts to do this in one stage were all failures because of fatal cellulitis and mediastinitis. He therefore devised a two-stage method, first placing two tubes of fascia around the esophagus, the outer tube being the longer. After several days he split the outer tube and removed the inner with the esophagus contained in it. By this method most of the animals survived, although stenosis developed in all cases. Later, Allen¹¹⁸ developed a technic for removing a portion of esophagus inside a fascial sleeve without splitting the sleeve. He placed two stout ligatures around the esophagus a short distance apart, enveloped this portion by a sleeve of fascia lata, and brought out the ends of the ligatures through the fascia. After a few days the ligatures were tied tightly, and the esophagus sloughed between them, the necrotic tissue being swallowed. In two of seven cases he failed to secure sloughing, because the ligatures were not tied tightly enough. In the remaining five cases, stenosis developed.

Neuhoof and Ziegler¹¹⁹ advocated a granulation tube method for reconstruction of the esophagus after resection. The first stage consisted of isolating the esophagus and packing it off from the surrounding structures. A week later, the packs were removed and granulation tissue had formed under them. The segment of esophagus was then excised, and a soft rubber tube securely sutured in its place. Granulations formed around the tube, which became loose and was removed. A fistula formed but finally closed completely. All the animals survived this two-stage operation, although all attempts to perform it in one stage ended in fatal cellulitis.

Schönbauer and Orator¹²⁰ performed experiments similar to those of Allen,¹²¹ using an inner and outer tube of peritoneum. One animal

lived for a year. The latest report in the literature on experimental surgery of the cervical portion of the esophagus is that of Carrington.¹²² After clamping the esophagus with two Kocher clamps, he placed a row of interrupted silk Lembert sutures all around and then cut through the esophagus between the clamps. The sutures were drawn tightly and the clamps released and withdrawn. The sutures were again drawn tightly as the clamps were removed, and this time were tied. Another similar layer of interrupted Lembert sutures was placed outside the first row. Each suture included muscle and adventitia. The wound in the neck was closed tightly. The experiment on only one dog was successful; fatal mediastinitis developed in all the other dogs, or, more commonly, sloughing of the esophagus that failed to hold. Carrington then changed his technic. After mobilization, the esophagus was surrounded by two narrow tapes about 5 cm. apart tied tightly enough to prevent leakage without injury of the muscular coat. An antiseptic solution, such as mercurochrome-220 soluble or a weak solution of iodine or chlorine, was introduced through a needle into the esophageal lumen between the two tapes. After time had elapsed for sterilization, the esophagus was divided and cut ends sutured together with three rows of sutures, the first continuous through all layers, the second an interrupted Lembert suture and the third consisting of six Lembert sutures which took in a long bite of tissue and were drawn only sufficiently tight to relieve the tension on the first two rows. Of eighteen such operations, he succeeded in nine; in most of the nine failures the esophagus was totally or partially divided, with resultant extensive cervical infection often associated with purulent mediastinitis. In one case only was there marked stricture, and even then the dog was kept in excellent condition. Carrington always sutured the cut ends of the esophagus with the viscus fully expanded, and it was on this part of his technic that he explained the absence of stricture in his results.

*Thoracic and Cardiac Portions (End-to-End Anastomosis).—*Although the cardiac portion of the esophagus is intraperitoneal, the operations on it and on the intrathoracic portion are so intimately connected that the operative procedures on these two parts of the esophagus will be considered simultaneously.

Resection of the thoracic and cardiac portions of the esophagus followed by end-to-end anastomosis has not yet passed beyond the experimental stage, as the clinical indications for its performance are not likely to be encountered frequently.

122. Carrington, G. L.: Experimental Surgery of the Esophagus: Some Factors and End Results, *Ann. Surg.* 86:505, 1927.

In 1901, Dobromysslów¹²³ reported the first successful intrathoracic suture of a resected esophagus. He made a large skin flap with its base posteriorly, extending from the sixth to the tenth rib vertically; it was about from 10 to 15 cm. in length. Resection of the ribs probably followed, although this was not mentioned. After incising the parietal pleura and laying bare the lower part of the esophagus, he divided the vagi and resected from 3 to 4 cm. He united the ends by two rows of silk sutures. Before the thoracic flap was sutured in place, the air was sucked out of the pleural cavity by negative pressure. Three weeks later, complete union of the suture line was found to have taken place, with slight proximal dilatation of the esophagus.

In spite of this apparent mastery of intrathoracic esophageal surgery, subsequent work in the same direction has not fulfilled the promise of success which Dobromysslów's performance seemed to give, even though shortly afterward the differential pressure chamber invented by Sauerbruch and the positive pressure apparatus of Brauer came into use and by their prevention of collapse of the lung during operation and pneumothorax afterward gave a great impetus to intrathoracic surgery.

In 1905, Sauerbruch¹²⁴ published two articles dealing with his experimental intrathoracic work on dogs. He introduced the intercostal incision in place of the more tedious and mutilating flap and resection method. Opening a pleural cavity through an intercostal incision is so simple and gives such excellent exposure of the thoracic part of the esophagus that it has been universally adopted in experimental work. Sauerbruch first of all tried end-to-end suture of the esophagus after resection and met with little success as his sutures continued to tear out.

In 1913, Omi and Karasawa¹²⁵ obtained some surprisingly good results in experimental operations on the thoracic portion of the esophagus. They used silk sutures in three layers, the first through the mucosa, the second through the muscle and adventitia and the third a continuous external Lembert suture. Of nine divisions of the esophagus with end-to-end anastomosis, seven were successful. In consequence of their results, they felt that a carefully made suture of the esophagus is sufficiently reliable to warrant its adoption in operations on human beings.

Thoracic and Cardiac Portions (Esophagogastrostomy).—Esophagogastrostomy as a method of restoring the continuity of the alimentary tract after resection of the thoracic portion of the esophagus has proved more popular than any other operation for this purpose.

Biondie,²¹ in 1895, was the first to carry out this procedure, performing it on dogs. To him also goes the credit of being the first to expose the esophagus by the transthoracic route. He employed a paravertebral incision followed by the resection of two or three ribs and incision of the parietal pleura. The stomach was pulled up through the diaphragm, the lower end of the esophagus cut through and the oral end sutured into the fundus of the stomach, which was then replaced in the abdomen. Biondie stated that the technic was difficult, particularly on account of the movement of the diaphragm, and pointed out that in the human subject the amount of esophagus to be resected for carcinoma might be so great that replacement of the stomach in the peritoneal cavity after the esophagogastrostomy might not be possible.

In 1904, Mikulicz¹²⁶ gave an account of his researches in intrathoracic surgery carried out in the Sauerbruch differential pressure chamber. He pointed out that it is difficult enough to reunite a transected esophagus because of tension, but much more difficult to reunite one in which a portion has been resected. Therefore he let alone the direct juncture of the two ends after resection and devised two other methods of dealing with the problem, the choice of method depending on whether the portion to be resected was at the lower end or higher up in the thorax. In the first case, after opening the pleural cavity, he pulled up the stomach and anastomosed it to the oral end of the resected segment of the esophagus. He found that in dogs and cadavers a good part of the cardiac end of the stomach could be drawn up into the pleural cavity. The wall of the stomach was stitched to the margin of the diaphragmatic opening, and the esophagogastric juncture remained within the pleural cavity. One dog in which this operation was performed had, at the time of writing, lived six weeks without any disturbance of digestion or nutrition. Another animal, in which 2.5 cm. of the lower end of the esophagus had been removed and esophagogastrostomy performed in this way, lived four weeks, and at necropsy the suture line was found to be intact and moderately stenosed. Disease of the lungs or pleura was not present. Mikulicz suggested that the displaced stomach might be replaced in the abdomen and the diaphragm sutured to the esophageal wall above the esophagogastric juncture which would thus become intraperitoneal. He performed this operation several times.

128. Voelcker: Ueber Exstirpation der Cardia wegen Carcinoms, *Verhandl. d. Verhandl. d. deutsch. Gesellsch. f. Chir.* 27:252, 1898.

In 1905, Sauerbruch,¹²⁴ because he considered tension the main cause of failure in his work on end-to-end anastomosis of the esophagus after resection, brought up the stomach into the pleural cavity and anastomosed the oral end of the resected segment of the esophagus to it both by end-to-end anastomosis and by implanting the esophagus into the stomach like the tube in a Witzel gastrostomy. In most of his experiments the sutures tore out. These failures led him to adopt the button for intestinal anastomosis. This proved so successful that he abandoned the use of sutures altogether. He stated that he had operated on eleven dogs without a death, although more than 7 cm. of the esophagus was resected. He also introduced a two-stage operation for the removal of the cardiac portion of the esophagus. The first stage consisted of thoracotomy with transection of the lower part of the esophagus and inversion of the lower end into the stomach followed by esophagogastrostomy. The second stage was undertaken after fourteen days, at which time laparotomy was performed, the stomach opened and the intragastric esophageal projection cut off; the stomach and laparotomy wound were closed. He performed this operation on cadavers and believed it to be feasible on the living subject. He mentioned clinical experience in three cases in which thoracotomy had been performed with a view to resection of esophageal carcinoma. All three tumors proved to be inoperable, and all the patients died.

In 1907, Wendel¹²⁷ operated on a patient who had carcinoma of the cardia and lower end of the esophagus; he used the transpleural route, bringing up the stomach through the diaphragm. After resection of the growth, he closed both the esophagus and the stomach and performed lateral esophagogastrostomy by means of a button. The patient died the next day of hemorrhage. This is the first case reported in which this operation was performed on a living subject.

In 1908, Voelcker¹²⁸ reported the first successful case of extirpation of a carcinoma of the cardia following two failures. After laparotomy through an incision parallel to the left costal margin, he cut the cardia below the tumor, freed the esophagus at its hiatus and pulled down about 4 cm. Then the esophagus was cut through above the tumor, and its oral end anastomosed to the stomach near its greater curvature. Gastrostomy was performed near the pyloric end. After four weeks of feeding through the fistula, nutrition by mouth was begun. In another month the fistula closed, and the patient ate normally. Data concerning this case have not appeared in the literature subsequently.

128. Voelcker: Ueber Exstirpation der Cardia wegen Carcinoms, Verhandl. d. deutsch. Gesellsch. f. Chir. **37**:126, 1908.

In 1909, Meyer¹²⁹ emphasized the importance of avoiding contamination of the mediastinum and pleura with the highly infectious esophageal mucous secretion, and devised a method of esophagogastrostomy whereby he sought to achieve this end. The essential points were: (1) drawing up the stomach into the pleural cavity and suturing the diaphragmatic peritoneum to the wall of the stomach; (2) division of the esophagus below the supposed tumor between a clamp below and a ligature above followed by inversion of the distal stump; (3) division of the esophagus above the supposed tumor between the clamp below and a ligature of absorbable catgut above; (4) incision of the stomach through serosa and muscularis and suture of the upper edge to the posterior wall of the esophagus with two layers; (5) opening of mucous membrane of the stomach and introduction of the ligated oral end of the esophagus, and (6) completion of the esophagogastric juncture by two layers of sutures between the lower edge of the incision in the stomach and the anterior wall of the esophagus. In six dogs operated on by this method, two functioning anastomoses were obtained. Meyer suggested: 1. Stricture may be avoided by dividing the esophagus with scissors instead of cautery, as burns show a greater tendency to contract than cuts, and that the esophagus should be divided obliquely instead of at right angles to its longitudinal axis if length permits. 2. Contraction of the gastric wound around the esophagus can be averted by elliptical excision of the serosa followed by a linear incision of the mucosa.

In 1909, Janeway and Green¹³⁰ operated on a large series of dogs, performing intrathoracic esophagogastrostomy alone; after resection of the lower part of the esophagus they used a specially designed button and reinforced the anastomosis thus made by suture. In sixty-nine operations, they successfully accomplished resection of the cardia and lower thoracic portion of the esophagus in four cases and lateral anastomosis without resection in six. They stated that their work demonstrated that speed, absolute asepsis and scrupulous care in the minimizing of trauma are essentials of success in esophageal operations. For these reasons, they adopted the button instead of sutures for anastomosis.

129. Meyer, Willy: *Oesophagogastrostomy After Intrathoracic Resection of the Oesophagus*, *Ann. Surg.* **50**:175, 1909; *Cancer of the Esophagus from the Standpoint of Intrathoracic Surgery: A Report of Four Resections*, *Surg. Gynec. Obst.* **15**:639, 1912.

130. Janeway, H. H., and Green, N. W.: *Experimental Intrathoracic Esophageal Surgery*, *J. A. M. A.* **53**:1975 (Dec. 11) 1909.

In 1909, Tiegel¹³¹ also used a modification of the button for intestinal anastomosis with some success, employing surgical procedures similar to those of Janeway and Green. He performed this type of operation once on man. The patient died eleven hours afterward.

In 1918, Bircher¹³² resected two carcinomas which involved the lower end of the esophagus and the cardiac part of the stomach. His technic was similar to that of Voelcker,¹²⁸ in 1908; he used the abdominal route and avoided opening the pleural cavity. In the first case, the esophagus was freed at its hiatus and easily drawn down above the upper limits of the tumor. This was then removed, the esophagus closed by ligature and the wound in the stomach closed, except for about 3 cm. near the greater curvature. Five long sutures were introduced into the wall of the esophagus, and an incision 2 cm. long was made on the anterior wall of the stomach about 5 cm. below the upper opening. Forceps were introduced through the lower opening in the stomach, passed through the upper opening and the long esophageal sutures seized. The esophagus was brought within the stomach through the upper opening by traction and made fast to the stomach after the manner of a Senn gastrostomy, three rows of sutures being used. A fourth row of sutures attached the stomach to the diaphragm all around the esophagus, thus completely covering it with peritoneum. The long esophageal sutures were cut, and the lower part of the opening in the stomach was used for a Kader type of gastrostomy. The patient, a woman, aged 63, was able to eat any kind of food one month after operation and survived for eighteen months. In the second case, Bircher used almost the same technic, except that he implanted the esophagus into the stomach after the manner of Witzel's gastrostomy. The patient died of cardiac insufficiency three days after the operation. At necropsy, the stomach was found adherent to the diaphragm. Bircher said that for primary union, operation should take place through the abdomen, and an attempt should be made to avoid the thorax entirely. Whereas Voelcker was satisfied with two layers of sutures for the implantation of the esophagus, Bircher used three, so that the esophagus was covered with peritoneum as much as possible.

In 1919, Bengolea¹³³ removed a carcinoma of the thoracic portion of the esophagus in a woman, aged 37, by the transpleural route, using a

133. Bengolea, A. J.: *Radical Resection of the Oesophagus for Carcinoma*, Surg. Gynec. Obst. 29:413, 1919.

Torek incision. The stomach was brought up through the diaphragm and esophagogastrostomy performed with the aid of a wooden bobbin placed in the oral end of the esophagus, which was invaginated into an opening on the fundus of the stomach. Closed drainage was used in accordance with Kenyon's technic. This proved inefficient, and, the wound had to be reopened, when serosanguineous fluid, which later became purulent, was evacuated. The patient died thirty-seven days after the operation.

In 1920, Kirschner⁶² used an abdominothoracic route to operate in two cases of carcinoma of the lower end of the esophagus also involving the cardiac part of the stomach. The incision began about midway between the xiphoid process and umbilicus, extended laterally to the left costal margin and from there along the seventh intercostal space. After dividing the diaphragm down to the esophageal hiatus, he freed and removed the tumor. He then mobilized the stomach according to his method, which has been described. The oral part of the esophagus was extracted through the neck, after the manner of Ach,¹¹¹ and brought downward under the skin of the chest. The mobilized stomach was then brought up onto the anterior thoracic wall subcutaneously, with the ultimate aim of joining the esophageal and gastric orifices by skin esophagoplasty, thus making a new artificial esophagus. The first patient died the day following operation, and the second survived five days. In the second case, the lower 3 cm. of the subcutaneous oral end of the esophagus necrosed, but the stomach was in good condition. Mediastinitis was present.

In 1922, Kümmell, Jr.,¹³⁴ introduced a new method for the operative treatment of carcinoma of the thoracic or cardiac portion of the esophagus. After freeing the esophagus in the neck and at the diaphragmatic hiatus, he mobilized the stomach after the manner of Kirschner. One index finger was inserted downward into the cervical wound along the esophagus and the other upward through the hiatus. Working with these fingers, he separated the esophageal wall from its surrounding mediastinal tissue until the two index fingers came in contact with one another, the esophagus being thus loosened in its bed. It was pulled upward until the cardia appeared in the cervical wound, so that the stomach now filled the mediastinum. The tumor was resected and esophagogastrostomy performed, the line of suture being extrathoracic and not to be replaced in the wound until it was known to hold. In this way Kümmell completed the immediate formation of a new esophagus in one stage; he believed that the stomach acts as a good tampon to stop bleeding from the esophageal bed. In spite of the fact that the

134. Kümmell, Hermann, Jr.: Operation des Oesophaguskarzinoms, *Deutsche med. Wchnschr.* **36**:1886, 1910; Ueber intrathorakale Oesophagusplastik, *Beitr. z. klin. Chir.* **126**:264, 1922.

five dogs and two patients operated on in this way died of rupture of the pleura with hemothorax within twenty-four hours of the operation, Kümmell was enthusiastic, and said that the advantages of his method lay in the avoidance of the larger mutilating operations; the extra-thoracic opening and juncture of the stomach and the esophagus, with prevention of the dreaded lethal mediastinitis due to suture or button insufficiency; the relatively rapid completion in one stage, and the immediate formation of a useful esophagus. In his experiments on animals and in clinical cases, he did not notice a disturbance in the nutrition of the wall of the mobilized and displaced stomach.

In 1923, Miller and Andrus⁵⁴ performed intrathoracic esophago-gastrostomy experimentally on dogs. They used the bulkhead suture of Halsted for the anastomosis. After the lower part of the esophagus had been resected and the cardiac stump inverted, the site on the stomach for the implantation of the esophagus was selected, and a circular area, about twice the size of the esophageal lumen, was outlined by an incision which passed through the serous and muscular coats. A temporary occluding ligature was obtained by threading a needle with strong silk and grasping the tissue in the bed of this incision at close intervals. The lumen of the esophagus was closed in a similar fashion at the upper limit of the proposed resection. Both the stomach and the esophagus were cut away just distal to the occluding ligatures; the resultant stumps were cauterized with cautery and phenol and brought into apposition by mattress sutures of fine silk. Just before the last two or three of these sutures were tied, the loop of each occluding ligature was drawn into plain view and cut and these threads pulled out; the lumen was thus reestablished. Care was taken to grasp the submucosa with the first sutures; then followed a row of sutures which grasped the muscular coats of the stomach and esophagus. The operation was performed eighteen times. Four dogs died within a few hours from shock and hemorrhage, and three other operations failed, two because of tension and one because of the occurrence of gangrene in the part of the gastric wall involved in the suture. All of the remaining eleven dogs showed an intact suture line and functioning anastomosis, despite the occurrence of death from infection, dilatation of the stomach and diaphragmatic hernia. Reference has been made to the work of these authors on the structure of the esophagus of human beings and the mobilization of the stomach. They concluded that resection and suture in situ of the esophagus were not beyond the bounds of possibility but rather offered definite grounds for hope.

In dealing with the resection of the lower part of the esophagus with subsequent esophagogastronomy, Heuer, Andrus and Bell,¹³⁵ in 1925,

135. Heuer, G. J.; Andrus, W. D. W., and Bell, H. G.: The Experimental Transplantation of the Diaphragm as an Adjunct in the Treatment of Lesions of the Lower End of the Oesophagus, *Ann. Surg.* 81:273, 1925.

sought to convert the procedure into an abdominal operation by the upward transplantation of the diaphragm, hoping in this way to avoid the well recognized danger of intraplanation of the diaphragm and to test the feasibility of the procedure, and later to perform intra-abdominal esophagogastrostomy after resection of the esophagus. In the first series of dogs, the thorax was entered on the left side, and the periphery of the diaphragm was detached from its costal attachment and sutured to the parietal pleura at a higher level. In the second series, these authors not only transplanted the left half of the diaphragm, but also divided it down to the esophageal hiatus, freed the lower part of the thoracic esophagus, and sutured the diaphragm to its wall at a higher level. In a third series, freeing the esophagus only at its hiatus accompanied the upward transplantation of the diaphragm. In the first series, good results were obtained. In the second, there was a mortality of about 30 per cent, the result of infection; postoperative vomiting was common, apparently due to constriction of the esophagus at its new hiatus. One case of diaphragmatic hernia occurred in this series. Two dogs comprised the third series; both recovered promptly from the operation without vomiting and were killed later. Diaphragmatic hernia was found in one case.

In six animals of the second and third series, intra-abdominal esophagogastrostomy was performed after resection of the lower part of the esophagus. The Halsted bulkhead type of suture was used as in the intrathoracic work of Miller and Andrus. An intercostal incision was made into the abdomen, and comment was made on the good exposure obtained and the fact that the operation was not difficult. The authors submitted a patient suffering from carcinoma of the lower end of the esophagus to this two-stage procedure. Although the history was only of two months' duration, the tumor was 7.5 cm. long and 5.5 cm. in diameter. Besides upward displacement of the diaphragm, the tumor was freed and the diaphragm sutured to the esophageal wall above it. The second stage was not undertaken, as the patient died forty-eight hours after the first operation. At necropsy, gangrene was found involving the proximal half of the growth and extending upward on the uninvolved esophagus to a point about 1 cm. above the new hiatus. At one point on the right anterolateral wall, perforation had occurred in the gangrenous area allowing leakage into the pleural and abdominal cavities. They concluded that it would be better to leave the freeing of the esophagus from its bed until the second stage.

In 1926, Fischer¹³⁶ introduced still another technic for the safe anastomosis of the esophagus and stomach intrathoracically. After

136. Fischer, Herman: Esophageal Implantation into Stomach After Intrathoracic Resection of the Esophagus for Carcinoma: A New Method, *Arch. Surg.* 12:241 (Jan.) 1926.

opening the pleural cavity by Sauerbruch or Torek's incision, he performed left phrenicotomy; this operation, by abolishing the respiratory movements of the side of the diaphragm, relaxes that structure, making easier the subsequent fixation of the stomach to its cut edge and ensuring undisturbed healing of the anastomosis. To effect this, he cut a sero-muscular quadrilateral flap from the upper part of the stomach with its base downward, and to the denuded submucosa he sutured the sides of the oral end of the esophagus, only its distal part entering the lumen of the stomach through a small incision in the submucosa, near the base of the flap. The flap was then sutured over the esophagus and broad Lembert sutures covering the flap finished the anastomosis. The suture which occludes the oral end of the esophagus is of plain catgut, which will be digested by the gastric juices in a few hours, and thus the esophageal lumen will be rendered patent. From experimental work done on the cadaver, Fischer has satisfied himself that his technic is feasible and not difficult.

In 1927, Gohrbandt¹³⁷ described an operation for carcinoma of the lower end of the esophagus somewhat similar to that of Kümmell¹³⁴ in that the mobilization of the viscus was carried out in the same way, namely, by the insertion of one forefinger down from the wound in the neck, and the other up through the diaphragmatic hiatus and by a circular and progressive motion eventually bringing about the meeting of the fingers near the level of the hilum. The esophagus was then pulled down and the tumor resected in the peritoneal cavity. A Babcock probe was then introduced through the neck along the side of the esophagus into the abdomen and firmly sutured to the distal part of the oral end. The probe was drawn up out of the wound in the neck, bringing the esophagus along with it. The esophagus was then transposed under the skin of the anterior thoracic wall. A portion of the stomach was drawn up under the skin for later plastic anastomosis with the ante-thoracic esophageal stump. The patient was to be nourished through a Witzel gastrostomy until the anastomosis was completed.

Gohrbandt reported six cases. In the first case, a carcinoma situated just above the cardia was resected intra-abdominally and esophagogastrostomy performed; the patient lived for six months after the operation and died of an intercurrent disease. By the tunneling method described, the author attempted the removal of five carcinomas. Of these, two proved to be inoperable; one patient died of pneumonia three days after the operation; in another the tumor perforated while being loosened, with a fatal result, and in a third case, death occurred on the ninth day following operation from a phlegmon of the ante-thoracic site of anastomosis of the stomach and esophagus.

Thoracic and Cardiac Portions (Transposition of the Oral End).—

In 1898, Levy¹³⁸ devised an ingenious, although rather impracticable, method of removing the thoracic part of the esophagus in dogs. He first performed gastrostomy and afterward severed the esophagus in the neck, suturing the oral end to the skin. He next brought a thread that had been introduced into the aboral end of the divided esophagus through a stomach tube out of the gastrostomy opening. He closed the upper end of the lower part of the esophagus in the neck by tying it with the thread. By pulling slowly on the thread, he inverted the esophagus and gradually pulled it out through the gastrostomy opening. When the cardiac part appeared, he ligated and cut the stump, sliding it back into the stomach. One of the animals lived six weeks. Levy tried this method on the cadaver, but he did not succeed in pulling out all the esophagus as he had done in dogs, as the outer longitudinal muscle fibers separated and remained behind. Consequently, he concluded that the procedure was not possible in man.

Mikulicz,¹³⁹ in 1904, was the first to introduce antethoracic subcutaneous transposition of the oral end of the esophagus after resection of its upper thoracic part. After intrathoracic resection, both ends were inverted and the thorax closed. The oral end of the esophagus was then brought out through an incision at the anterior border of the left sternomastoid muscle. Mikulicz said that because of the loose attachment of the esophagus in the mediastinum he succeeded without difficulty. Then the bared esophageal stump was brought under the skin in front of the pectoralis major and its end fixed to the edges of a small transverse incision over the second intercostal space. The wound in the neck was closed tightly. It was later proposed to make a plastic juncture between the esophagostomy and a gastrostomy opening which, of course, had to be performed to provide the animal with nourishment temporarily.

In 1904, Kelling¹⁴⁰ also introduced a method of transposition of the oral end of a transected esophagus. He believed that the opening of the esophagus within the thorax was the chief factor of the high mortality consequent on intrapleural esophageal operations, since infection of the pleura or mediastinum was almost certain to occur. Therefore, he sought to operate aseptically in the pleural cavity and mediastinum by refraining from opening the esophagus here. He

performed an intrathoracic operation and loosened the tumor from its surrounding tissues, closing the thorax immediately afterward. The abdomen was then opened and the esophagus freed from the diaphragm. The cardiac portion of the esophagus was divided and the distal end closed; in the oral end he placed a wooden cylinder, and after tying the esophagus around this, he enclosed the end in a rubber membrane. He now pulled on a thread which had previously been passed down the esophagus and fastened to the wooden cylinder. The latter was pulled up, drawing with it the esophagus which was pulled out through an incision in the neck and after resection of the tumor drawn through a tunnel under the skin of the chest, being sutured to the edges of a transverse incision in the skin. He performed a skin esophagoplasty between the esophagostomy and the gastrostomy openings, with poor results.

In 1910, Wendel¹⁴¹ performed operations in two cases of thoracic esophageal carcinoma, in each case bringing one end of the resected esophagus into the thoracotomy wound with a view to a future plastic operation. In the first case, the carcinoma was at the height of the bifurcation of the trachea; after the esophagus had been cut through below the tumor, the aboral end was brought forward into the thoracotomy wound in the anterior axillary line and sutured in position. The oral end of the esophagus was brought upward through an incision in the neck after the preliminary freeing from its surrounding tissues, and the tumor was then resected extrapleurally. The esophagus was then stitched into the wound in the neck. Death occurred from bilateral pneumothorax nine hours after the operation. In the second case, the carcinoma was in the lowest part of the thoracic portion of the esophagus. After the esophagus was cut through above the tumor, the aboral end was closed and the oral end was brought forward and sutured into the thoracotomy wound. Through a laparotomy incision, the tumor was pulled down and extirpated together with part of the cardiac end of the stomach. The wound in the stomach was reduced in size to that of a gastrostomy opening and sutured into the abdominal wall. The patient survived the operation only twenty-four hours. Collapse of the left lung was found at necropsy.

In 1913, Ach¹⁴¹ and Zaaier¹⁴² succeeded in removing a carcinoma of the cardiac portion of the stomach and esophagus. Torek⁹⁷ removed a carcinoma from the thoracic portion of the esophagus. Ach planned his operation so that the pleural cavity should not be opened, working

only in the neck and abdomen; he decided to remove the upper portion of the esophagus by invagination. He performed the operation first on dogs and then on four patients. A long laparotomy incision was made parallel to the left costal margin. The cervical portion of the esophagus was then exposed and mobilized by blunt dissection. The costal margin was retracted well upward so that good exposure was obtained. The diaphragm around the esophageal hiatus was freed and the tumor pulled down, both vagi being cut. The esophagus was clamped above the tumor, and a ligature about 1 meter long was tied around the esophagus above the clamp. A second clamp was applied above the tumor and the esophagus divided between them. A long flexible steel rod with an eye in its end was passed down the esophagus until it came in contact with the ligated oral end. A suture was passed through the esophageal wall, and the eye of the rod and was left about 12 cm. long. The rod was carefully withdrawn; the suture, as it was pulled taut, inverted the walls of the esophagus. The whole esophageal tube was thus extracted until the lower invaginated end appeared in the cervical wound, when the extraction ceased. The long ligature was secured from the invaginated funnel and fixation suture through the eye of the sound cut by the anesthetist. By pulling on the ligature, the invaginated esophagus was evaginated through the cervical wound and drawn through a tunnel under the skin of the sternum to a small transverse incision through which it was brought onto the surface of the chest. The tumor was then resected, the wound in the stomach closed and gastrostomy performed. Ach reported three cases in which he had performed operations by this method. In his second and third cases, instead of performing gastrostomy, he brought up the distal part of the stomach remaining after resection on to the anterior thoracic wall and placed it subcutaneously, thus performing an inferior esophagoplasty. All three patients died within fourteen days. He also reported fifty-five operations on dogs, most of which were intrathoracic resections, with success in only three.

Later, Ach¹⁴³ reported a fourth case of carcinoma of the cardiac portions of the esophagus and stomach in which operation was performed by his combined cervical and abdominal technic. He succeeded in removing the tumor, but the patient died seventeen days after the operation from "insufficiency of the gastric fistula."

Zaaijer¹⁴⁴ followed a plan similar to that which had been used in 1911 in his case of "oesophagostomia thoracalis" and performed the

operation in two stages. The first consisted of extensive subperiosteal resection of the lower six ribs on the left side, from the angle forward for about 10 cm. This caused sinking in of the wall of the chest, thereby rendering the esophagus and cardia much nearer the surface of the chest. After the patient had recovered from this operation, the second stage was undertaken. A long curved incision was employed, beginning in the hypochondrium below and extending upward and backward in the posterior axillary line as far as the lower angle of the scapula, and in this way laparothoracotomy was performed. The diaphragm was cut through down to the esophageal hiatus and there freed. The lower part of the esophagus was mobilized and brought, with the stomach, into the wound. Zaaier next cut through the stomach below the tumor, closed it and returned it to the abdomen, and then sutured the diaphragm. The esophagus with the tumor at its lower end was brought out through the wound, and the parietal pleura was sutured to the wall of the esophagus about 4 cm. above the upper margin of the tumor. Then followed closure of the pleural and peritoneal cavities. The tumor was removed by cutting through the healthy esophagus above it with thermocautery after a few days. The distance between the thoracic esophagostomy opening and the gastrostomy opening was provisionally overcome by an apparatus so constructed that food could be taken by mouth. The patient left the hospital fourteen days after the second operation.

Torek,⁹⁷ too, preferred to perform extrapleural resection of the esophageal carcinoma in his case, in order to do away with leakage from the oral end after resection. He also decided to pay particular attention to the avoidance of rough handling of the vagi. The patient was a woman, aged 67, with a carcinoma of the thoracic portion of the esophagus just below the lower border of the transverse arch of the aorta. The thoracic incision ran the whole length of the seventh interspace and extended upward posteriorly; the seventh, sixth, fifth and fourth ribs were divided near their tubercles. On retraction good exposure was obtained. The tumor was fairly fixed, and there was some difficulty in separating it from the arch of the aorta and the left bronchus, the latter sustaining a longitudinal cut during the dissection requiring repair by silk suture, which acted satisfactorily. Torek then dissected the esophagus free from its attachments all the way up to the neck, divided it with cautery a safe distance below the carcinoma after double ligation, and brought out the oral end with its tumor through an incision in the neck at the anterior border of the left sternomastoid. Thus the danger of infection of the mediastinum and pleural cavity from leakage of the oral end of the esophagus was obviated. The remaining lower end was crushed, ligated and invaginated, and the thorax closed without drainage. The portion of the esophagus which

was hanging out of the neck was drawn through a tunnel under the skin between the wound in the neck and a transverse incision over the second intercostal space; it was then brought to the surface through this incision, the carcinoma cut off, and the fresh rim of the esophagus sutured to the edges of the transverse incision. The wound in the neck was then closed. The patient made a good recovery and was nourished through the gastrostomy tube until the eighth day, after which time the outer end of this tube was introduced into the esophagostomy opening for the purpose of allowing the patient to carry out mastication and deglutition in the normal manner. Soon afterward she was able to take all varieties of food which could be chewed into an almost fluid state. In 1925, Torek¹⁴⁵ published a follow-up report on this case, telling of the patient's happy state and freedom from recurrence, and a year later stated¹⁴⁶ that she had died of pneumonia at the age of 79, after having been in good health up to three days before death. The patient had lived more than twelve years after the operation. Torek's case thus takes its stand as being the most outstanding and impressive in thoracic esophageal surgery. It is the only case in which the results obtained through surgical procedures have definitely exceeded those obtained by palliative measures and those obtained in many cases of carcinoma of more accessible organs when treated surgically. Although it is well known that for one patient, for example, with gastric or mammary carcinoma who survives operation for as long as twelve years, there are many who, although less fortunate, will live for three, four or five years; never before or since Torek's operation have there been any such promising results from the surgical treatment of esophageal carcinoma.

Unger¹⁴⁷ performed the same operation as did Torek, and his patient died five days afterward.

In 1914, Baumgartner¹⁴⁸ operated on a man with carcinoma of the thoracic portion of the esophagus. The patient died six hours after the completion of the operation. Baumgartner employed a technic similar to that of Torek but with minor differences. He chose to operate on the right side, mainly because of the absence of the aorta

and the ease with which the azygos vein can be dealt with. He not only cut ribs near their tubercles, but resected one of them to obtain better exposure. He finally resected the tumor intrathoracically before transposing the oral end of the esophagus subcutaneously. Necropsy showed that the right pleural cavity contained about 0.75 liter of bloody fluid; a vessel which could be said definitely to be the source of the hemorrhage was not found.

In 1915, Meyer¹⁴⁹ reported on further experience with resection of the thoracic portion of the esophagus for carcinoma in four cases. All of the patients died. In three cases, he planned to restore the continuity of the esophagus with the aid of an extrathoracic Beck-Jianu tube. In the other case, he performed the Torek operation. Meyer, commenting on drainage of the pleural cavity after operations on the esophagus, said that his experience had convinced him that when Torek closed the thoracic cavity without drainage he was favored with remarkable luck. Meyer believed that it is the surgeon's duty to drain the thorax immediately after the operation in all cases of resection of the esophagus for carcinoma.

In 1922, Hedblom¹⁵⁰ resected a carcinoma involving the lower end of the esophagus and cardiac part of the stomach. He employed Zaaier's method with the modification of performing the thoracoplasty in three stages instead of in one stage as Zaaier had done, resecting the fifth to the eleventh ribs from their angles to the costal cartilages. His incision for resection extended from a point to the left of the median line below the costal margin upward and backward to the level of the fourth rib in the midaxillary line. Through this he opened both peritoneal and pleural cavities, split the diaphragm down to the hiatus and, after mobilizing the lower end of the esophagus, removed its lower 4 cm. together with the cardiac part of the stomach. The stomach was sutured to the lower part of the wound below the diaphragm and the esophagus to the wound above that structure. A month after the resection the patient had gained several pounds and was taking soft food by mouth, the esophageal and gastric stomas being connected by tube.

In 1922, Levy¹⁵¹ reported a series of operations performed on dogs in 1913 and 1914. He began to resect the cardiac portions of the

esophagus and stomach by a two-stage operation, the first being extensive thoracoplasty for the purpose of collapsing the wall of the chest and thus bringing the esophagus nearer to the surface of the chest and facilitating its exposure. He treated the resected portion of the stomach and esophagus in the same manner as Zaaizer had done. In ten operations there were six successes; the four failures were due to empyema. He pointed out that in this operation the stomach can be brought up to any level required by the esophagus, as the diaphragm can be sutured to the wall of the chest at any desired height. Levy made a small plastic skin tube to connect the esophageal and gastric orifices.

In 1924, Lotheissen¹⁵² reported ten cases of carcinoma of the thoracic portion of the esophagus in which Torek's methods of operating were used. With the exception of two patients whose lesions were inoperable and who lived one and three months respectively after operation, all died within a few hours. Necropsy showed variously mediastinitis, empyema or collapse of the lung.

In 1925, Eggers⁹⁸ successfully removed a carcinoma of the thoracic portion of the esophagus by Torek's technic. Both vagi were sharply divided without disturbing the patient's condition. He employed closed drainage, and on the first day about 200 cc. of serosanguineous fluid passed through the tube; about 50 cc. passed on the second and third days, after which the drainage ceased; the tube was removed on the fourth day. The lower portion of the oral end of the esophagus had to be removed on account of gangrene. Connection between the esophageal and gastric orifices was established by a rubber tube, as in Torek's case. The only further mention of this case which seems to have appeared in the literature was made by Torek,¹⁴⁶ who, in 1926, stated that the patient was then living and in good health more than a year after the operation. It is of interest that the patient was young (aged 38) and that the symptoms had existed for only six weeks.

Thoracic and Cardiac Portions (Esophagoplasty by Means of Skin or Fascia).—In 1917, Höfer and Kofler¹⁵³ described an original method of extrapleural resection of carcinoma of the thoracic portion of the esophagus with repair of the esophageal defect by skin esophagoplasty. Their work was done on the cadaver. They cut a triangular skin flap with a vertical base of 14 cm. and a length of 20 cm. The base was to the right of the vertebral column, and the flap extended over this onto the left thoracic wall. The flap was raised and reflected to the right. Then followed the removal of the portions of the right

152. Lotheissen, Georg: Zur Radikaloperation des Speiseröhrenkrebses, Arch. f. klin. Chir. **131**:200, 1924.

trapezius and underlying rhomboid muscles which were exposed by the reflection of the flap. The ribs exposed by this procedure were resected for 10 to 12 cm. subperiosteally, the intervening intercostal muscles cut away and the pleura and esophagus exposed. Several centimeters of the azygos vein was removed, the carcinoma freed from its attachments and the esophagus separated above and below the tumor sufficiently to allow the introduction of the skin flap under it. The apex of the flap was pulled to the left of the vertebral column as far as possible; the upper edge was brought forward on both sides of the esophagus and sutured in front; the lower edge was treated in the same manner, so that the esophagus lay in a trough of skin. The tumor bearing part of the esophagus was to be removed at a second operation, and the esophageal defect repaired by the plastic formation of a skin tube, the posterior wall of which had already been made. Höfer and Kofler stressed the importance of the exact localization of the tumor by the esophagoscope and radiography so that the flap may be outlined correctly. The right side is preferred because of the absence of the aorta. Muscle is not included in the flap, because it is prone to necrosis if separated for any length.

In 1921, Lilienthal,¹⁵⁴ unaware of the work of Höfer and Kofler, devised a similar operation and tested it on the cadaver as they had done, but he was able to apply it clinically with some success. Lilienthal used a rectangular flap, the upper border of which was the eighth interspace, the lower, the tenth rib, its outer limit the midaxillary line, and its base about 3.75 cm. from the vertebral column. Whereas Höfer and Kofler attacked the esophagus from the right side, Lilienthal did so from the left, giving as his reasons the importance of the aorta as a landmark, the greater distance from the important veins and thoracic duct, and the avoidance of the difficulty of freeing the pleural fold which crosses the median plane at this point. After freeing the esophagus, the skin flap was placed in position, lying between the esophagus and the right vagus (the left vagus was not seen), the cuticular surface next to the esophagus and the terminal end turned round it and held in position by a silk suture running from its tip to the inner part of the wall of the chest, the trough of skin thus formed to be completed into a tube by division of the pedicle later. Several days afterward the tumor was resected, and later the pedicle was divided and turned outward to meet the terminal end of the flap. The pedicle, however, showed a marked tendency to return to its normal position. Before

154. Lilienthal, Howard: Carcinoma of Thoracic Oesophagus Extrapleural Resection and Plastic: Description of an Original Method with Report of a Successful Case Without Gastrostomy, *Ann. Surg.* 74:259, 1921; Carcinoma of the Thoracic Oesophagus: Final Notes and Post-Mortem Examination in the Case Reported in the *Annals of Surgery*, September, 1921, *ibid.* 76:333, 1922.

healing finally took place by granulation, five months had elapsed since the first operation. Contraction at the upper mucocutaneous juncture necessitated the passage of sounds. The patient lived for eleven months after being dismissed from the hospital. A tracheo-esophageal fistula, caused by recurrence of the growth, and terminal pneumonia were the cause of death.

Lilienthal mentioned having on four occasions, explored the mediastinum for carcinoma of the esophagus; in every case, the tumor had extended beyond the wall of the viscus. Three of the patients died of mediastinitis through injury to the esophagus during attempts to isolate it. In the fourth case, the cause of death was unknown.

In 1921, Budde,¹⁵⁵ working on the cadaver with a view to replacement of the resected part of the esophagus, built a pedicled tube of skin, fascia and muscle around a glass rod. Part of the thoracic portion of the esophagus was then resected extrapleurally and the tube implanted between the cut ends.

In 1922, Allen¹¹⁷ resected a small piece of the thoracic portion of the esophagus and repaired the defect with fascia lata. He performed seventeen one-stage operations, with uniformly fatal results. The cause of death was empyema and mediastinitis due to leakage from the esophagus. By his two-stage method of double fascial tubes with subsequent opening of the outer tube and resection of the inner tube and that portion of esophagus inclosed by it, he performed six operations, of which four were successful. Both failures were due to empyema and mediastinitis after the first stage before the esophagus was opened.

Later, in 1925, Allen¹¹⁸ operated on the thoracic portion of the esophagus in dogs in a manner similar to that used on the cervical portion. He employed the two-stage operation to remove a section of the esophagus without actually opening its lumen at either operation, depending on the tying of ligatures, which were planted around the esophagus inside the fascial sleeve, to cause necrosis of that part of the viscus between the ligatures. In four such operations, he failed to secure sloughing in one. The other three were successful, but were followed by definite stenosis. He attempted this operation in a case of carcinoma of the thoracic portion of the esophagus, but the tumor proved to be inoperable.

Comment.—An effort has been made, by this comprehensive review of the literature, to give an idea of the wide extent to which esophageal surgery has been practiced for the removal of carcinoma, and to show that the reason it has not succeeded has not been due to the lack of either effort or ingenuity.

155. Budde, Werner: Zur Frage des plastischen Ersatzes schleimhautbekleideter Röhren: I. Urethra virilis; II. Oesophagus, Deutsche Ztschr. f. Chir. 161:1, 1921.

There are two aspects of carcinoma regarding which opinions are divergent: that of early diagnosis, and the virulence of the growth.

It is well known that exploratory operations show most carcinomas to be inoperable, and many surgeons maintain that earlier diagnosis would bring the majority of these neoplasms within the limits of operability. This opinion warrants investigation. It is noticeable in published reports of cases that patients with esophageal carcinoma rarely consult a physician at the onset of symptoms, but generally wait for months rather than weeks. Can anything be attained by the education of the laity in regard to the early symptoms of esophageal carcinoma, such as commencing difficulty in swallowing solid foods and perhaps a sense of substernal oppression or later the regurgitation of ropy mucus into the mouth, so that such patients may be seen, for example, within a week of commencement of symptoms? The answer to this question depends on two points: the actual cause of the symptoms and the virulence of the growth. With regard to the former, one can say the symptoms are due to mechanical obstruction only. This means that the growth, even when the earliest symptoms appear, must have extended sufficiently to produce obstruction. Unfortunately, carcinoma of the esophagus grows not only inward, encroaching on the lumen, but extends outward simultaneously into the surrounding tissues, laterally to involve the whole circumference and upward and downward. Carcinoma of the esophagus, therefore, will be without symptoms until it has reached considerable size and is firmly fixed to surrounding tissue, or until the contraction of fibrous tissue develops in an attempted natural cure.

The degree of malignancy is of the greatest significance. The belief that these growths are relatively benign and slow-growing has been handed down to us, based chiefly on the frequently reported inability of observers to demonstrate metastasis at necropsy; many present-day surgeons persist in holding this opinion. Abel,³ for instance said that he intends to prove that carcinoma of the esophagus is a relatively benign, mild type of malignant growth. On the other hand, the opposite view is slowly gaining ground. Souttar,¹⁵⁶ from his clinical experience, expressed the belief that carcinoma of the esophagus is of high grade malignancy, and that it fails to produce widespread secondary deposits only because death occurs early. Just as long as this problem can be discussed only on clinical grounds, there will be divergence of opinion. Broders' ¹⁵⁷ method of grading the malignancy of tumors, however, aids considerably in deciding the issue. According

156. Souttar, H. S.: Treatment of Carcinoma of the Oesophagus: Based on 100 Personal Cases and Eighteen Post-Mortem Reports, *Brit. J. Surg.* **15**:76, 1927.

157. Broders, A. C.: Squamous Epithelioma of the Lip: A Study of Five Hundred Thirty-Seven Cases, *J. A. M. A.* **74**:656 (March 6) 1920.

to the degree of differentiation of the cells, any carcinoma can be placed in one of four grades arranged in increasing order of malignancy; thus, mild, slow-growing tumors are graded 1 and the most malignant tumors are graded 4. This method, introduced in 1920, has received a fair trial, and in the hands of experts has proved to be reliable. I am indebted to Broders and Vinson¹⁰³ for allowing me to use their unpublished data concerning the malignancy of esophageal carcinoma. In a series of 220 cases of carcinoma of the esophagus observed at the Mayo Clinic, they found that more than 90 per cent of such tumors were graded 3 and 4, that is, they were of the most malignant types; cases graded 1 were not found. This is significant in considering the chance of success of surgical procedures, for it means that by the time a carcinoma has extended sufficiently to produce obstruction (at which time the earliest symptoms will appear) it will have spread beyond the limits of surgical removal, except perhaps in a few cases.

Other data compiled by Broders and Vinson strengthen this opinion and throw light on the question of metastasis. They found that in forty-two cases in which postmortem examinations were made, twenty-seven showed metastasis, whereas of the last fifteen cases of this series metastasis was found in fourteen.

Because of the anatomic structure and relationships of the esophagus, the highly malignant carcinomas of the organ, the frequent occurrence of metastasis, the danger of fatal infection and the mutilation which must always cause great shock, surgical removal of these tumors cannot be expected to be attended with any degree of success. Although a successful case may occasionally be reported, this will never justify routine surgical exploration and the attempted removal of esophageal carcinoma with its appalling mortality. The only operation which has attained even a small degree of success is extirpation of a cervical esophageal carcinoma with subsequent double flap skin esophagoplasty after the manner first introduced by von Hacker, or the single flap method of Lane¹¹⁰ and Ach.¹¹¹

Thus, it appears that only palliative measures can be applied as a routine in the treatment of patients with this disease. These include the use of radium, deep roentgen rays, diathermy, intubation, gastrostomy and dilatation. All of these methods have their advocates and their opponents, and a voluminous literature has accumulated concerning them. As this phase is nonsurgical, its discussion has been omitted as being outside the scope of the subject of this article.

DIVERTICULA

Despite the fact that the so-called esophageal (pulsion) diverticula have been proved definitely to be pharyngeal, their surgical treatment is always considered a branch of esophageal surgery. Because they are

not uncommon and because the results of their surgical treatment are highly satisfactory, it was felt that they should be considered here.

There are a few important contributions to the early literature concerning diverticula that are worthy of note. Bell,¹⁵⁸ in 1816, was the first to draw attention to their occurrence. He performed necropsy in a case in which there had been trouble with dysphagia during life and found a posteromedial pouch at the upper end of the esophagus. He likened the condition to the hernial protrusion of mucosa which occurs in the bladder in cases of urethral or prostatic obstruction. Later he suggested that the surgical treatment should consist in emptying the sac by the establishment of a fistula.

Rokitansky,¹⁵⁹ in 1840, was the first to draw attention to the occurrence of two types of diverticula and classified them from an etiologic standpoint into two groups: (1) those due to traction exerted on a portion of the esophageal wall from without, and (2) those due to pressure within. Those in the first group he called traction diverticula and those in the second pulsion or pressure diverticula. Since Zenker and von Ziemssen,¹⁶⁰ in 1877, reported on their study of twenty-seven postmortem specimens, and described the etiology, pathology, symptoms, etc., of the condition, little has been added to the knowledge of the disease except the advances in the surgical treatment. These authors stated that the radical cure of pulsion diverticula by surgical measures from without was one of vain hopes, yet they were hopeful that even this operation conducted on Lister's plan might some day be performed without danger. Such was the state of surgery fifty years ago. The monographs on diverticula by Starck,¹⁶¹ in 1900, and Rosenthal,¹⁶² in 1902, are worthy of mention as comprehensive studies on the subject.

Although Bell¹⁵⁸ surmised the pharyngeal origin of the large pulsion diverticula, and Zenker and Ziemssen proved it, for a long time it was commonly accepted that the diverticula originated in a small triangular area at the upper end of the esophagus posteriorly just below the inferior constrictor muscle of the pharynx where the divergence of the esophageal musculature caused a weak spot. Keith¹⁶³ and others, however, have definitely pricked the bubble of the Lainer-Hackermann triangle, as this area is called, and have proved beyond question that

these diverticula are formed by the evagination of the mucous membrane through the posterior pharyngeal wall between the upper and lower parts of the inferior constrictor muscle, the main function of the former being to seize the bolus of food and force it into the esophagus, while the latter acts as a sphincter to the upper orifice of that viscus. Such diverticula are, therefore, true sacculi.¹⁶⁴

Traction diverticula are usually found on the anterior wall of the esophagus near the bifurcation of the trachea, and they usually originate from a localized adhesion of the esophageal wall to the surrounding parts, sometimes the result of inflammation of one of the bronchial glands. The walls of the diverticula consist of all the coats of the esophagus, and they are therefore true diverticula.¹⁶⁴ They rarely give rise to clinical symptoms, although occasionally they may become enlarged, the increase in size being due to the arrest of food in the diverticulum and the gradually increasing pressure resulting therefrom. Oekonomides¹⁶⁵ gave the name of "traction-pressure diverticulum" to this condition.

Sauerbruch¹⁶⁶ reported a case in which a traction diverticulum had ruptured into the lung, causing abscess and the formation of fistula which necessitated operation. Ordinarily, however, such diverticula do not require surgical intervention.

The several methods of choice in the surgical treatment of pulsion diverticula (sacculi) are: extirpation in one or two stages, invagination and diverticulopexy (sacculopexy). Apart from the local operative measures, however, the preoperative preparation is important and consists of thorough oral hygiene and the lavage of the sac with mild antiseptic solutions. Some surgeons recommend preliminary gastrostomy in elderly and debilitated patients.

The earliest recorded surgical assault on a pharyngeal diverticulum was that of Nicoladoni¹⁶⁷ in 1877. His procedure consisted in opening the sac and establishing a fistula, thus putting into practice Bell's suggestion. The patient died from pneumonia six days after the operation. Shortly afterward a few surgeons attempted to remove radically these protrusions by the one-stage method, the essentials of which are the exposure and separation of the sac and its removal by cutting through the neck. The surgical approach to a diverticulum is exactly the same as that employed in cervical esophagotomy, the incision usually being

along the anterior border of one or the other sternomastoid muscle, usually the left, because the majority of these pouches protrude on that side. C. H. Mayo,¹⁶⁸ however, advocated incision in the line of the natural crease of the neck, one-third being behind the anterior border of the sternomastoid. The sac is exposed by dissecting deeply between the carotid sheath laterally and the trachea and thyroid gland medially. After it has been separated from the surrounding structures by gentle blunt dissection, it is severed through its neck, usually between clamps or ligatures. The treatment of the stump then remains a matter of choice, but ordinarily interrupted sutures inverting the mucous membrane are used and followed by a further line of suture through the musculature. Although this operation is apparently ideal from the technical standpoint, it has a disadvantage which, although sometimes overcome, may prove fatal. Because of the absence of a serous coat, the line of suture is relatively slow in healing, and so the possibility of leakage through the sutured pedicle must always be considered and a drain inserted. Leakage will cause infection which is likely to spread down the fascial planes of the neck into the mediastinum, with fatal results.

Niehans,¹⁶⁹ in 1884, was the first surgeon to perform a one-stage operation for the removal of a diverticulum. The patient had a goiter as well. Niehans first removed the goiter, and after fifteen days, the symptoms not being relieved, excised the diverticulum with thermocautery between two ligatures. The patient was fed by stomach tube for a few days, and on the eighth day drank milk which flowed out of the cervical wound. Hemorrhage from the superior thyroid artery caused death on the twenty-fourth day after the removal of the sac.

In 1892, von Bergmann¹⁷⁰ reported the first successful extirpation of a diverticulum (6 cm. long), although a fistula persisted for several months. Kocher¹⁷¹ reported two cases in 1892. In both, operation was successful; although temporary fistula developed in one case, the wound in the other case healed by primary intention. In 1893, Dugge,¹⁷² in reporting a fatal case in which operation was not performed, commented on the small number of cases reported; he succeeded in finding only twelve cases in the literature of the six years preceding

1893. Since that time, the number reported has increased continually. In 1903, Butlin¹⁷³ reported eight cases in which he had operated during the preceding ten years. In 1910, Stetten¹⁷⁴ reviewed all the cases he could find in the literature up to that time, and his statistics throw some light on the results of surgical measures in this sphere. In a group of sixty patients, fifty were cured and ten died, a mortality of 16.6 per cent. In a group of forty-eight patients on whom the one-stage operation was performed, the mortality was 18.7 per cent.

In 1918, Judd¹⁷⁵ reported a series of 35 cases from the Mayo Clinic with only 2 deaths. Two years later¹⁷⁶ he reported an additional 17 cases with only 1 death, making 52 cases in all. In 1923, C. H. Mayo¹⁷⁷ stated that the total number of patients operated on at the clinic had reached 74 without further mortality. In 1921, Deis¹⁷⁸ noted 134 cases in the literature; in 88 of these, the one-stage operations had been performed with 10 deaths, a mortality of 11.3 per cent, which is below that reported by Stetten for similar cases. In 22 of the cases reviewed by Deis, the two-stage operation had been performed without deaths.

The two-stage method was introduced by Goldmann,¹⁷⁹ in 1909, its purpose being to minimize the danger of spreading infection along the fascial planes of the neck consequent on leakage from the diverticular pedicle. By this method the sac, after being freed, is brought out into the operative wound and left there for about two weeks, during which time granulations form and wall off the fascial planes of the neck. The sac is then removed and the neck sutured. Since its inception by Goldmann, the two-stage method has been widely adopted and also modified in different ways by various surgeons. Goldmann, after freeing the sac, tied the pedicle with a silk ligature, packed a tampon around the sac and closed the wound in the skin, leaving a small opening for the removal of the tampon. The tampon was removed and the sac cut off a few days later. A fistula formed and drained for two months. Deis¹⁷⁸ was of the opinion that allowing the necrotic

sac to separate by itself after ligating its neck is a safe procedure. Von Beck¹⁸⁰ also recommended this method, and reported seven cases with five successes; two patients died from pneumonia. C. H. Mayo,¹⁷⁷ after delivering the sac into the wound, sutures its neck to the sternomastoid or to the platysma muscle with a few interrupted catgut sutures, and the wound in the neck is closed around the neck of the sac. Ten or twelve days later the sac is again freed, then excised and the opening in the esophagus and the wound in the neck closed. Judd¹⁷⁵ illustrated this method. Murphy¹⁸¹ advocated twisting the sac, packing around it, and later amputating it with suture of the pedicle. Wilkie's¹⁸² method offers still greater protection against the danger of cellulitis and mediastinitis. After the sac is freed, the margins of skin are sutured to its body. The second stage, performed several days later, consists of incising the base of the sac down to the submucous plane and separating the mucosa by blunt dissection for about 5 cm. from the surface of the skin. The free edges of the mucosa are then united by a roll-in suture of chromic catgut and further invaginated by interrupted sutures. The stump is allowed to retract and the wound in the skin is partially closed by sutures. Wilkie reported two cases; in the first case the wound was dry in less than three weeks, and in the second a small fistula persisted for about five weeks.

Although the two-stage method is the more popular, the one-stage method still has its advocates. In 1910, Stetten¹⁷⁴ declared that the method of Goldmann did not require serious consideration and reported a case of his own in which the patient left the hospital with the wound completely healed sixteen days after the one-stage operation. In 1922, Bensaude and Grégoire,¹⁸³ also expressed belief that the one-stage operation is best and that the two-stage operation means taking unnecessary precautions. C. H. Mayo,¹⁷⁷ however, stressed the advisability of the two-stage operation if a large pouch is present, particularly if it extends down into the thorax. Recent reports by Lahey,¹⁸⁴ and by Crile and Dinsmore¹⁸⁵ showed excellent results obtained by the two-stage method.

In 1896, Girard¹⁸⁶ treated two patients successfully by obliterating the cavity of the sac by invagination. By invaginating the sac by purse-string sutures, repeated as many times as is deemed necessary, its cavity is obliterated without being opened. The inverted sac either atrophies or sloughs off. Although this operation has the advantage of eliminating every possibility of infection, its disadvantage is that the polypoid projection produced by the inversion of the sac may, if large enough, produce occlusion of the pharyngeal lumen. This, then, would seem to limit the operation to small sacculi. There remains the question of recurrence after this operation. In 1912, Waggett and Davis¹⁸⁷ reported a case in which the former had operated by Girard's method with apparent success. Ten months after the operation, the patient said that after sneezing violently he felt "something break" in his neck. A diagnosis of reexpansion of the invaginated sac was made and operation undertaken. It was found that the diverticulum had much the same appearance as before the first operation. Radical extirpation by the one-stage method was undertaken with success, the wound healing by first intention. Bevan,¹⁸⁸ however, operated on what was evidently a large sac, and if inversion by repeated purse-string suture had been carried out, it is probable that pharyngeal occlusion would have resulted. To overcome this difficulty he used purse-string sutures for the outer part of the sac, but he reefed the inner part with longitudinal sutures, leaving the sac compressed against its attachment. In a later article,¹⁸⁹ he described a modification of this method for use with a large diverticulum. He first cuts through the middle of the sac by clamp and cautery, and after removing the outer part invaginates the remaining inner part. Von Beck¹⁹⁰ also tried the invagination method, with success. Besides being adaptable to cases of small diverticula, it is also useful if the patient is old and debilitated.

Diverticulopexy appears to have found a definite place in surgical treatment for pharyngeal diverticulum. The procedure was first proposed by Schmid¹⁹⁰ in 1912, who, on the cadaver, fixed the bottom of the sac at a higher level than its neck, the sac not being opened. This

operation was first practiced on the living subject by Hill ¹⁹¹ in 1918. The sac was dissected free and the fundus stitched to the left side of the inferior constrictor muscle, with at least temporary relief of symptoms. König ¹⁹² fixed the sac to the hyoid bone with success.

In 1922, Van den Wildenberg ¹⁹³ reported that he had had recourse to diverticulopexy with complete success seven times. In four cases, he performed only this operation. In the remaining three he used it as a first stage, excising the pouch afterward at periods varying from eight days to three months. The second operation proved to be much more simple than the first, as the sac was found at once and only a small incision was needed. Diverticulopexy is not a radical procedure and Van den Wildenberg advised its use only as the first operation of a two-stage procedure; he further stressed this point in a later communication ¹⁹⁴ as a result of one case of recurrence after the operation. In one case, Hautant, ¹⁹⁵ besides performing diverticulopexy, ligated the neck of the pouch, his object being to prevent the reflux of food into its cavity, notably in postoperative vomiting. Deglutition took its normal course at once. One might think that there would be danger of sepsis from decomposition in this closed cavity. Hautant's patient, however, had enjoyed excellent health for six months at the time of report.

In summarizing the present status of the surgical treatment of pharyngeal sacculi one might say that the two-stage method can be done with so little risk that it has been adopted practically universally. Van den Wildenberg ¹⁹⁴ has introduced sacculopexy as the first stage in two-stage removal. Statistics show that the one-stage method, although ideal from the technical standpoint, means unnecessary risk.

Invagination and sacculopexy have the disadvantage of not being radical operations. The former, however, is well suited for small sacculi, and although large ones can be treated in this manner, this procedure is not likely to be preferred to extirpation. Sacculopexy, by its simplicity, the absence of the risk of sepsis and because of the results already attained by this method, seems likely to become a more popular operative procedure as time goes on. It would seem to be ideal for old and debilitated patients.

EXPERIMENTAL INVESTIGATION

The object of the experimental work undertaken was to obtain if possible a successful method of suture for end-to-end anastomosis of the esophagus, at first after simple division, and, if this proved satisfactory, after resection.

The difficulties which beset the surgeon in operating on the esophagus have been discussed. They exist because of the unique anatomic structure and relationships of the viscus. In my earliest experiments on the anastomosis of the divided organ, I was particularly impressed with the poor nature of the blood supply. Fatal cellulitis and mediastinitis were the outcome, and necropsy showed not only sloughing of the cut ends of the esophagus constricted by the sutures, but discoloration of the mucous membrane for several centimeters above and below the level of division which corresponded to the length of the esophagus necessarily isolated for the performance of the operation. As these experimental operations had been carried out with the usual aseptic precautions, it was felt that the primary factor causing the ensuing fatal infections was not the contamination of the surrounding tissues with esophageal secretion at the time of operation, as many authors seem to believe, but the sloughing at the line of anastomosis due to constriction of its blood supply by the sutures, with resultant leakage of infective esophageal secretion.

This led me to investigate the blood supply to the esophagus in the dog. After several unsuccessful attempts with prussian blue and carmine gelatin injections, it was decided that the most satisfactory method would be the injection of a radiopaque medium. That used was a mixture of barium sulphate and gelatin, made up according to the directions given by Gross¹⁹⁶ as follows:

Soak 300 Gm. of fine French gelatine for two hours in 1,200 cc. of distilled water. To this add 1,000 Gm. of finely powdered barium sulphate, 500 cc. of distilled water, and 2 Gm. of thymol. Heat over a water bath until the gelatine dissolves and stir until the whole mass becomes a homogeneous milky fluid. Filter through two layers of Victoria lawn.

The specimen for injection was obtained in a manner similar to that used by Demel¹⁹⁷ in his work on the blood supply to the human esophagus. A recently killed dog was used. A median line incision was made which extended from the chin to the pubis, the skin was reflected widely on each side and the sternum and chondral parts of the ribs removed. The tongue was severed from its attachments, the posterior

196. Gross, Louis: *The Blood Supply to the Heart in its Anatomical and Clinical Aspects*, New York, Paul B. Hoeber, 1921, vol. 16, p. 171.

197. Demel, Rudolf: *Die Gefäßversorgung der Speiseröhre: Ein Beitrag zur Oesophaguschirurgie*, Arch. f. klin. Chir. 128:453, 1924.

pharyngeal wall cut through, and the whole of the cervical viscera removed. The ascending part of the aorta was cut between ligatures and the heart removed; each lung was removed by cutting through the hilum just distal to a ligature and through the pulmonary ligament. By the removal of the heart and both lungs, the vascular bed to be injected was considerably diminished in size. The parietal pleura was incised on both sides about 2.5 cm. from the vertebral column. The intercostal vessels were ligated and cut from above downward to the level of the diaphragm, which was then separated from its costal and vertebral attachments. The hepatic artery was ligated and cut and the gastrohepatic ligament divided; the first part of the duodenum was cut between ligatures; the splenic artery was ligated and cut close to the spleen, and the branches of the gastro-epiploic arteries descending into the greater omentum were ligated and the omentum divided. The superior mesenteric, inferior mesenteric and renal arteries were then ligated and cut; the lumbar branches of the aorta were dealt with in the same manner and the aorta itself was severed just above its bifurcation.

In this way a specimen was obtained consisting of the whole length of the esophagus, the trachea, stomach and diaphragm, together with all the arteries from which the esophagus receives its blood supply.

A cannula was tied into the lower end of the aorta and the vascular bed of the specimen was washed out thoroughly with water injected into the cannula by a syringe. In order to render the vascular bed water-tight it was necessary to ligate such arteries as the internal and external carotids, the subclavians, the vertebrales, the transverse cervical and scapular arteries, the internal mammary arteries and any others through which water was seen to escape during the washing process.

The specimen was now ready for injection and was placed in the dish containing hot water. The injection apparatus was rendered as air-tight as possible, and when the valve on top of the oxygen tank was opened, gas passed into the carboy. The pinchcock was opened slightly; the mercury in the limbs of the manometer immediately showed a difference of from 10 to 20 mm.; the effect of this pressure acting on the surface of the injection medium was to force the latter out of the bottle, into the rubber tube to be connected with the cannula in the specimen. Before this connection was made, however, the mixture of barium sulphate and gelatin was allowed to run out of the rubber tube, as otherwise the air contained in the tube would be forced into the specimen in front of the injection medium which would then be unable to fill the vascular bed completely. As soon as the connection was made, the medium began to flow into the aorta and its branches. The pinchcock was opened gradually until the mercury in the limbs of the manometer showed a difference in height of 200 mm.,

and the medium was seen to fill the finer branches of the vascular bed. This pressure was maintained for one hour.

The aorta was then ligated and the cannula withdrawn. The specimen was placed in 10 per cent solution of formaldehyde for twenty-four hours, at the end of which time the injected barium sulphate and gelatin had solidified and roentgenograms were taken. Figures 1 and 2 show specimens prepared by this method. Several other specimens were injected and photographs taken. One specimen after injection was cleared by the Spalteholz method which consists of dehydration by

Fig. 1.—Roentgenogram of injected specimen.

alcohol, and then immersion in benzene and synthetic oil of wintergreen. The specimen was first placed in 40 per cent alcohol and changed every two days into an alcohol of 10 per cent additional strength, ending with immersion in absolute alcohol for four or five days. Next the specimen was immersed in benzene for two days, after which it was placed in oil of wintergreen. Clearing commenced almost immediately and continued until fine arterial twigs could be seen clearly. Oil of wintergreen forms the medium in which such a cleared specimen may be mounted permanently.

Figures 3 to 9 represent only a small part of the material which was studied and which was found to show the following points of interest:

1. The roentgenograms showed the poverty of the blood supply to the esophagus. This is apparent when the small amount of injection medium capable of filling the arteries of the esophagus is contrasted with the large quantity necessary to fill those of the stomach.

2. The blood supply is segmental. Most of the arteries divide into ascending and descending branches, and those of one particular segment anastomose with the arteries supplying the segments above and below.

3. The anastomotic network between the arteries of adjacent segments is scanty.

Fig. 2.—Roentgenogram of injected specimen. Cervical portion of trachea removed.

4. The arteries on entering the wall of the esophagus quickly pass into its submucous layer and there ramify. Microscopic sections of an esophagus, the arteries of which have been injected, show this layer to be by far the most vascular.

5. According to the distribution of its blood supply, the esophagus may be divided into the following segments: cervical, upper thoracic, middle thoracic, lower thoracic and abdominal.

The cervical segment is the most poorly supplied with blood of all the segments of the esophagus. Its upper and middle parts derive their blood supply from descending branches of the thyroid artery (this

artery corresponds to the superior thyroid artery in man and alone supplies the gland, there being no inferior thyroid artery in the dog). The lower part of this segment is the most vascular and receives its blood supply from ascending branches of the artery supplying the upper thoracic segment. Occasional twigs are given to the middle part of the cervical segment by the common carotid arteries.

In the esophagus of man, Demel found that three constant branches from the inferior thyroid artery supplied the lower part of the cervical segment, the first of these originating from the center of the ascending

Fig. 3.—Roentgenogram showing large-sized stomach tube in esophagus of dog (dog 1, table) twenty-two days after operation. The tube passed down without any difficulty.

portion, the second from the median bend and the third from the lower ascending portion close to the subclavian artery.

The upper thoracic segment is the part of the esophagus at the level of the innominate artery. From about the middle of the artery a constant tracheo-esophageal branch arises which soon divides into two branches, one supplying the esophagus and the other the trachea. The former divides into ascending and descending branches. Those which ascend anastomose with the descending branches from the thyroid artery

and with those from the common carotid when present. The descending branches anastomose with branches of the arteries which supply the middle thoracic segment. Demel did not find this tracheo-esophageal artery in his specimens from human subjects. Its place is taken apparently by the esophageal branches of the inferior thyroid.

The middle thoracic segment corresponds to the level of the bifurcation of the trachea. It receives its blood supply from two esophago-tracheal arteries which were found to arise either from the second

Fig. 4.—Cervical portion of esophagus removed from dog (dog 1) eighty-three days after operation; *a*, line of anastomosis.

Fig. 5.—Mucosal surface of specimen shown in figure 4. The line of anastomosis, *a*, is seen as a pale transverse ridge over which the epithelium has grown completely; absence of stenosis (compare with figure 9).

intercostal artery near its origin or directly from the aorta at this level. Sometimes the arteries arise separately and at other times they spring from a common trunk only 2 or 3 mm. in length. They pass forward and downward and shortly before reaching the esophagus divide into two branches, an esophageal and a tracheal, the latter ascending to the bifurcation and the former entering the esophagus on its lateral aspects and then dividing into ascending and descending branches. The anasto-

mose above with twigs from the esophageal branch of the innominate artery and below with those from the arteries which supply the lower thoracic segment. This segment is the most vascular part of the canine esophagus. Demel found that it is also the most vascular part of the esophagus of man, which fact is of interest as the majority of esophageal carcinomas are found there.

The lower thoracic segment extends from just below the level of the bifurcation of the trachea to the diaphragm, and derives its blood supply from two arteries which arise from the third left intercostal artery near its origin or directly from the aorta at this level usually by a common trunk which is short although longer than that of the tracheo-esophageal arteries supplying the segment above. It divides into its two branches,

Fig. 6—Longitudinal section through line of anastomosis of specimen in figures 4 and 5, complete epithelial overgrowth; the muscular coat is thickened at this point due to the method of suture; outside the muscular coat and covered by adventitia are the remains of a silk suture encapsulated by cellular fibrous tissue.

which pass downward, forward and to the left until they reach the lateral aspects of the esophagus where they enter it and divide into ascending and descending branches. To similar arteries in specimens from human subjects Demel gave the name "*arteriores esophageae propriae*." The lowest part of this segment has the poorest blood supply of the whole length of the thoracic portions of the esophagus.

In the arrangement of the tracheo-esophageal arteries and the *arteriores propriae* as described, slight variations may occur. Their mode of origin has been commented on. Sometimes one of the branches of the tracheo-esophageal trunk will supply only the esophagus. At other times one of the *arteriores propriae* will send an ascending branch

to the bifurcation of the trachea (fig. 1). Thus, there is apparently a compensatory arrangement in this group of arteries.

The abdominal segment is the part of the esophagus below the diaphragm. It is dependent for its blood supply on small ascending twigs which arise from the left gastric and left inferior phrenic arteries near their origins. They pass upward on the esophageal wall to anastomose with the descending twigs of the arteriores propriae.

Figure 7

Figure 8

Fig 7—Cervical portion of esophagus distended with water; specimen removed from dog (dog 2, table) seven days after operation. Absence of stenosis, *a*, oral end, *b*, line of anastomosis

Fig 8—Mucosal surface of specimen shown in figure 7. Epithelial overgrowth has not taken place (compare with figure 5) Absence of stenosis, *a*, oral end; *b*, line of anastomosis

These investigations show that the blood supply to the esophagus in the dog closely resembles that in man (as described in detail by Demel), the only difference being the replacement of the branches from the inferior thyroid artery by those from the tracheo-esophageal branch of the innominate artery.

The ability of a suture line to hold together the two cut ends of any viscus depends primarily on the conservation of a sufficient blood supply to the line of anastomosis. These studies clearly demonstrate the poverty of the blood supply to the esophagus and in consequence show that unless special care is exercised it would be an easy matter to produce enough constriction of the blood vessels by the sutures to cause sloughing of the two cut ends, which would result in the extravasation of the esophageal secretion with fatal infection.

Other factors that would appear to contribute to success are the smallness of the suture material and the putting at rest of the organ for a reasonable time after operation so that tension on the suture line is avoided. The structure of the esophageal wall must also be taken into consideration. The muscular coat forms poor material for suture as it will easily tear. The submucous layer, on the other hand, is strong and

Fig. 9.—Mucosal surface of cervical portion of esophagus removed from dog (dog 5, table) thirty-six days after operation. Marked stenosis, with dilatation above the stricture. Epithelial continuity established over line of anastomosis; *a*, oral end; *b*, line of anastomosis.

its inclusion in the sutures is essential if the two cut ends are to remain in apposition. Aseptic technic with careful packing off of the divided esophagus from the surrounding tissues is a *sine qua non*. With these factors in mind, the following technic was devised for the end-to-end anastomosis of a divided esophagus:

The material used was Japanese blood vessel silk, no. 0 (which is finer and stronger than the thinnest catgut) on a fine straight needle, no. 12, about 1.25 cm. long.

The anastomosis was made by two rows of sutures. The inner row consisted of eight or nine interrupted inverting mattress sutures, spaced evenly around the circumference and passing through the whole thickness of the esophageal wall, thus including the strong submucous layer

in their grasp. The needle pierced the wall about 2 mm. from the cut edge, and each suture included about 2 mm. of the circumference in its grasp. Thus, while the blood supply to those parts of the esophageal wall caught in the sutures was constricted when they were tied, that of the remaining greater part of the circumference was unharmed. The outer row was a continuous suture passing only through the muscular coat and avoiding the submucosa where the vessels ramify. This outer row inverted the inner row and made the anastomosis water-tight.

It was decided first to attempt division at different levels of the esophagus, beginning with its cervical part, to ascertain the effect, if any, of the varying blood supply on the anastomosis. The operative procedure on this part of the esophagus was carried out as follows:

The anterior part of the neck was shaved and the animal anesthetized in the cabinet ordinarily used for this purpose at the Institute of Experimental Surgery and Pathology.¹⁹⁸ After the animal had been properly arranged on the operating table, the anesthetic was administered by the intratracheal method. The part shaved for operation was then treated with two coats of 2 per cent iodine in ether and draped with sterile towels. A median line incision was made which extended from the cricoid cartilage to the jugular notch. After hemostasis had been accomplished, sterile towels were clipped to the edges of the wound, thus excluding the skin from the area of operation. The incision was continued down to the trachea in the median line between the hyoid depressor muscles. The pretracheal fascia having been cut through, a finger was inserted backward along the left side of the trachea and hooked around the esophagus which was then brought up into the wound. The recurrent laryngeal nerves which are adherent to the esophagus were stripped off from it and the viscus isolated by blunt dissection. This method of approach to the esophagus is much easier than that between the sternomastoid muscle laterally and the hyoid depressor muscles medially. Enough of the esophagus was isolated to admit the application of two intestinal clamps between which the esophagus was to be divided, the required length being about 5 cm. These clamps were used only to occlude the lumen of the esophagus and so prevent the escape of secretion into the field of operation from either above or below. The pressure exerted by them was not sufficient to injure the blood supply. After the clamps were applied, the esophagus was thoroughly packed off in a manner similar to that used when gastro-enterostomy is to be performed. The part of the viscus between the clamps was then cut through by scalpel or straight scissors, and the ends turned upward and thoroughly wiped. The technic which has been described for end-to-end

198. Mann, F. C.: Anesthesia in Experimental Surgery, *Am. J. Surg.* 34: (Anesthesia Supplement) 73, 1920.

anastomosis of the cut ends of the esophagus was then applied. Four or five interrupted inverting mattress sutures were inserted through the posterior half of the circumferences of the cut ends, the clamps were held close together to take tension off the sutures, which were then tied. The anterior halves of the circumferences were then drawn together by four or five similar sutures, each being tied before the next was inserted. The clamps were taken off at this stage. The second row, a continuous suture inverting the first, was begun at the center of the anterior part of the line of anastomosis. Traction toward the left was put on the short end while the suture was continued to the right. Each bite of the needle included as much of the esophageal muscular coat as seemed necessary to prevent the cutting through of the silk. When a point about half way around the circumference was reached, the needle was passed under the esophagus to the left side. Traction was then exerted on the short end toward the right and the suture continued from left to right until the starting point was again reached. In this way the entire circumference of the esophagus was sutured with ease. This method of performing the outer continuous suture is technically easier than putting in its posterior half before the introduction of the mattress sutures, as in gastro-enterostomy.

The esophagus was then replaced in its bed; the hyoid depressor and sternomastoid muscles fell into place; three or four interrupted catgut sutures were used to draw together the deep cervical fascia, and the skin was closed by a continuous suture of buttonhole-twist thread. Hemorrhage during the operation was not great.

The postoperative treatment is of great importance in the success of the operation. It consisted in placing the esophagus at rest for seven days by not giving any food or water by mouth during this period. Water balance and nutrition were maintained by 10 per cent dextrose solution in physiologic solution of sodium chloride administered intravenously in quantities varying from 200 to 350 cc. each day, according to the weight of the dog. At the end of this time the animal was allowed a mixture of milk and syrup for another period of seven days, after which ordinary food was given.

I performed six operations by this method on the cervical portion of the esophagus at different levels (table). Stricture occurred in two of the animals, probably because too much of the circumference of the esophageal wall was grasped by some or all of the mattress sutures, an imperfection in technic which can be remedied with care.

In only one of the six experiments did infection supervene. In the remaining five, the blood supply to the line of anastomosis was conserved sufficiently to prevent sloughing.

In the experiment in which sloughing of part of the line of anastomosis occurred, the operation was performed on the most vascular (lower) region of the cervical part of the esophagus; since a successful operation was performed later in the same region, the failure can be attributed only to faulty technic.

Four of the operations in which sloughing did not occur were performed on the least vascular (upper and middle) regions of the cervical part of the esophagus.

Results of the Division of the Suture of the Cervical Portion of the Esophagus

Dog	Date of Operation	Level of Division of Cervical Portion of Esophagus	Results		Comment
			Infection	Stenosis	
1	12/6/27	Middle	—	—	Animal in good health to time of death (27-28), eighty-four days after operation; large sized stomach tube passed down esophagus without difficulty twenty-two days after operation
2	12/16/27	Upper	—	—	The plethysmograph had been applied to the spleen previously; the animal died suddenly seven days after operation; necropsy did not reveal the cause of death, a few adhesions were found around the esophagus at a level of the line of anastomosis, stenosis was absent
3	12/16/27	Lower	±	—	At operation this part of the cervical portion of the esophagus was found to be noticeably more vascular than the upper and middle parts (in agreement with observations in investigation of the blood supply to the esophagus); swelling of the neck fifth day after operation; 150 cc. of foul-smelling pus evacuated; animal died the seventh day after operation; necropsy showed sloughing of the anterior half of the line of anastomosis, posterior half intact, infection of the neck remarkably localized, in spite of low level of site of operation mediastinitis was not found
4	12/20/27	Lower	—	—	Animal alive and in good health; no dysphagia
5	12/21/27	Middle	—	±	Animal swallowed only fluids up to time of death, thirty-six days after operation; necropsy showed bilateral bronchopneumonia (? aspiration), marked above stricture
6	12/21/27	Upper	—	±	Animal alive, fluids only, but swallowing

The results of these operations show that this method of suture allows for a supply of blood to the line of anastomosis plentiful enough to prevent sloughing and ensure union, even when the esophagus is divided in the least vascular regions of its cervical part.

Further experimental surgery along these lines, which will include resection of the cervical portion of the esophagus, together with division and resection of its thoracic portion, is being carried out.

SUMMARY

An outline is given of the development of surgery of the esophagus with a comprehensive survey of the literature on the subject up to the end of 1927.

The problems which have rendered surgical procedures in this sphere so difficult and which still remain to be overcome have been discussed.

They lie in the anatomic structure and relationship of the esophagus and in the risk of fatal infection of the pleura and the cellular tissue of the neck and mediastinum.

The numerous operations devised and performed for the extirpation of esophageal carcinoma have resulted in an appalling mortality.

It is pointed out that such tumors are highly malignant, that they metastasize readily, and that by the time they give rise to symptoms they usually have spread beyond the limits of surgical removal.

The various methods used for the plastic formation of a new esophagus in cases of benign cicatricial stricture believed to be impermeable are described. There is a mortality of 20 per cent in the cases reported in the literature; in addition, several operations are necessary and they require months for completion, and completion is by no means assured. These reasons render plastic operations *undesirable procedures, to be avoided by early and adequate dilation and by impressing on the patient the necessity for further dilation at stated intervals.*

It would seem, too, that plastic operations have been undertaken unjustifiably in many cases, the inability to pass the smallest sound being taken as the indication of impermeability. In nearly all such cases, however, a swallowed silk thread can worm its way through the stricture and then be used as a guide for sounds.

Pharyngeal diverticula are considered to be true sacculi and traction pouches to be true diverticula. The latter rarely require surgical treatment. The results of removal of pharyngeal sacculi by the two-stage method show that it is associated with lower mortality than the one-stage operation, and in consequence is practiced more commonly.

A method of suture which has given satisfactory results is described for the end-to-end anastomosis of a divided esophagus. The suitability of this method as a means of anastomosing the two cut ends of an esophagus after a portion of it has been resected is being investigated.

A NEW ABDOMINAL INCISION *

J. TATE MASON, M.D.

SEATTLE

The type of incision employed is one of the most important factors in the ultimate results obtained in operations on the abdomen. Sir Barkley Moynihan, in his chapter on abdominal incisions, stated that if the incision is improperly made by the free division of muscular fibers or a wilful and unnecessary severing of nerve trunks a weakened area is left in the abdominal wall, which may cause the patient distress of even greater severity than did the condition which primarily necessitated the operation. It would seem that the qualifications which should commend an abdominal incision are: that it give adequate exposure, disturb a minimum number of nerve and muscular fibers and be so placed that closure is simple, and that a minimum number of postoperative hernias follow its use.

I feel that there have been too many postoperative hernias following midline incisions or long incisions of the right rectus muscle and that a change from the old routine incision of the upper part of the abdomen should be made. I believe that the incision which I wish to present may be closed with less tension on the edges of the wound, will cut no muscles and will disturb few nerves; these are factors which should produce fewer postoperative adhesions, less abdominal pain and fewer postoperative hernias.

My experience again would lead me to believe that there are a large number of weak scars of the upper part of the abdomen following all types of incisions of the upper part of the abdomen now in use. Sloan's¹ report of weakened abdominal walls in 80 per cent of his cases coincides with my experience. In many instances there was no hernia but the abdominal wall was so thin that the constant wear and tear of a number of years, plus any slight strain, might be followed by a definite hernia. Observers, from Abel² in 1899 to the present time, have reported from 2 to 8.9 per cent of postoperative hernias. These percentages must be based on short postoperative periods of observation. My statistics would lead one to believe that the percentages, when based on five year periods of postoperative observation, are much higher.

* Submitted for publication, March 16, 1929.

2. Abel: *Progressive Medicine*, 1899.

The rule that the frequency of hernia increases in proportion to the square of the length of the incision does not indicate as great incidence in the long incision as really exists. In the olden days, when drainage of the gallbladder was done more frequently than now, one frequently saw a short incision, approximately 3 inches (7.6 cm.) in length. One did not see many hernias or weak scars among these patients, but at the present time, when cholecystectomy plus appendectomy is in vogue, a great number of hernias occur in the long straight incisions, usually a little to one side of the rectus muscle.

The nerve supply of the rectus muscle is so situated that splitting the muscle for any distance will sever the nerve fibers and leave the inner side of the rectus devoid of nerve supply. In most of the cases in which a wide vertical splitting of the rectus fibers has been performed, atrophy of the inner side of the muscle occurs, owing to the cutting of nerves and to the dissociation of muscles and nerves at the time of the operation. One was at a loss to understand, at first, why these patients left the hospital with a fairly firm wound, and, as time passed, subsequent observations revealed a progressive thinning of the wound until a hernia developed or became imminent. Now it is realized that these developments were the result of muscle atrophy. This realization encouraged the effort to refrain from splitting the muscles if possible, and thus to conserve the nerve supply.

As Moschcowitz³ stated:

The rectus muscle is attached only anteriorly to the sheath and even here only at the three so-called lineae transversae, while its attachment to the posterior sheath is very loose and readily broken up. The lineae transversae, before mentioned, do not penetrate the entire thickness of the muscle but merely the anterior third or half.

On investigation I found these statements to be "anatomic facts," and thus I obtained the idea of rolling the muscles away from the posterior sheath, leaving it attached in its outer two-thirds to the anterior sheath, as will be described later in a drawing.

In addition, interesting investigations have been made by Professor Stopford and Mr. A. H. Southam,⁴ who describe them as follows:

We first examined the results of the incision passing through the outer third of the rectus muscle, splitting the fibers, and where two, or often more, nerves had been divided. This incision is easily and rapidly made and gives good access to most of the abdominal viscera. We found there was a very definite sensory loss, as shown by anesthesia and analgesia in the strip of skin between the scar and the

lineae alba. After about fifteen months, however, the sensory loss becomes negligible, as far as ordinary testing can determine, probably owing to regeneration of nerve fibers.

In all these cases there was a marked loss of function of that part of the rectus muscle lying between the point where the fibers were split and the midline. This may be fairly extensive or confined to one segment of the muscle, depending upon how many nerves have been divided. It is present from the outset and persists for a considerable period. In a few cases there was a slight bulge when coughing but for the most part the loss of muscle function could only be detected when the patient raised the head and shoulders from the couch. The functional results from the patient's point of view were excellent, and after secure suture and healing by first intention, no disability was apparent from the abdominal scar.

We next followed up the results obtained by the paramedian or rectus slide incision with outward displacement of the muscle and its nerves. In these cases, for some reason not readily explained, the sensory loss is insignificant from the start. We found that in this group the rectus muscle on the side of the scar functions normally throughout, and there is no weakness discoverable after this operation.

Sloan¹ has given some interesting and instructive information on the subject of vertical and lateral tension in an abdominal incision. By measuring the tension with spring scales attached to several forceps with lateral, transverse and "L"-shaped incisions, he found that the amount of tension increases approximately in proportion to the square of the length of the incision. In an incision 3 inches long, with the patient lightly anesthetized, there is about 30 pounds (13.6 Kg.) and in a 5 inch (12.7 cm.) incision there is about 80 pounds, (36.3 Kg.) tension. Another interesting point is that there is about thirty times as much tension from side to side on a longitudinal incision as there is from above and below on a transverse incision. The tension of the transverse incision can be lessened by a suitable posture, which has been suggested by Farr, in operating with the patient under local anesthesia.

I have found that the tension depends somewhat on the musculature of the abdominal wall. In a small woman with a thin abdominal wall, it is rarely possible to get more than from a 15 to a 20 pound (6.8 to 9 Kg.) pull on the scales when she is lightly anesthetized, while on a muscular man I have seen the scales go up as high as from 50 to 60 pounds (22.7 to 27.2 Kg.), approximating a 6 inch (15.24 cm.) incision during the time he was straining.

As to the frequency of postoperative adhesions, it cannot be stated correctly that one incision has any advantage over another, because many adhesions are due to causes far removed from the type of abdominal incision and the method of closure. I have noticed, however, that in most cases in which there was a straight, long, weak incision, or in which there was evidence of a hernia, adhesions to the parietal peritoneum were present in close proximity to the incision. From these

observations, it would seem that a strong firm scar is of primary importance in the prevention of postoperative parietal adhesions.

I shall describe a longitudinal and transverse incision that has been developed in the clinic within the past two years. It has been used forty-six times and, excepting one case in which the patient had a severe bronchopneumonia and coughed incessantly for days, has given uniform satisfaction. In this one case there was a slight separation of the transverse suture line, which was resutured immediately with a satisfactory result. This incision is based on the principle of the Kammerer incision, that of displacing the rectus muscles outward, and of the Mayo operation for the relief of umbilical hernia.

OPERATIVE PROCEDURE

A description of this incision follows:

Step 1: The incision is begun just to the left and below the ensiform cartilage. It is carried downward through the skin and fat to the median of the fascia covering the left rectus muscle. The incision is lengthened downward along the rectus muscle to within 2 or 3 cm. of the umbilicus; then it is carried straight across the midline to the right rectus muscle and downward along that muscle from 4 to 6 cm.

Step 2: The anterior surface of the left rectus muscle is cleared of fat. The fascia is also cleared well in the transverse and right rectus incisions.

Step 3: The fascia on the inner third of the left rectus muscle is split the length of the incision. A transverse incision is then made from one rectus muscle to the other. The fascia on the inner one third of the right rectus muscle is then opened.

Step 4: The muscles are rolled outward and the peritoneum opened behind the left rectus muscle. A transverse incision through the peritoneum just above the umbilicus completes the incision. This gives ample exposure for any operation in the upper part of the abdomen and allows the operator to reach and remove a retrocecal appendix in the lower right quadrant.

The following is the method of closure: The patient is placed in a flexed position. The transverse incision is first closed before the peritoneum is sutured. The suture is made after the manner of the Mayo repair of umbilical hernia, imbricating the upper with the lower flap securely with from two to three mattress sutures. The approximation of this part of the wound is facilitated by the flexed posture that has been advocated by Farr. The peritoneum of the upper part of the wound is then closed separately. The muscles are allowed to drop back in their sheaths and the aponeuroses are sutured in the usual manner.

CONCLUSIONS

A new abdominal incision is described for which the following advantages are claimed: The exposure is greater than in any incision that I have ever tried. It is easy of closure. It is a combination of a longitudinal and a transverse incision, allowing the wear and tear of years of tension on a scar line to fall on both of the recti muscles

Fig 1.—Section through the lower portion of the costal arch, demonstrating the nerve supply to the rectus abdominis muscle.

Fig. 2.—The dotted lines indicate where the incision is to be made.

Fig. 3.—Superficial dissection, showing the right rectus muscle and the lineae transversae in the upper part of the wound, and the sheath of the right rectus in the lower part of the wound.

Fig. 4.—The anterior sheath of the rectus muscle is severed to just above the umbilicus, and the left rectus is retracted to the outer side. The diagnosis is made through this upper incision when the operator decides if the incision should be extended to a transverse and right rectus. The dotted line indicates the complete incision. In the insert, a section is shown with the muscle retracted. X indicates the position of the incision through the posterior sheath.

instead of on one. The strain of abdominal pressure is exerted on the scar in three different places, practically as if there had been three incisions. I have designated the incision as a "three in one incision" because while the abdomen is open it is really one continuous incision, but after closure the effect is that of three distinct suture lines. I believe that this incision lessens the number of postoperative hernias, because after closure the effect is that of three short incisions. As mentioned it has been shown that "the shorter the incision the fewer the hernias." Also, only a few twigs of nerves need be severed and no muscle fibers are cut.

OPERATIVE RELIEF FROM PAIN IN LESIONS OF THE MOUTH, TONGUE AND THROAT*

WALTER E. DANDY, M.D.

BALTIMORE

The recent development of an operative attack on the trigeminal and glossopharyngeal nerves at the brain stem for the cure of trigeminal and glossopharyngeal tic douloureux¹ at once suggested the permanent relief from pain in which the peripheral distribution of both of these nerves are responsible, namely, in chronic ulcers, burns from radium or malignant lesions of the tongue and throat.

The exact form of treatment by which relief from pain is to be sought will necessarily depend on the character, location and rate of growth of the lesion and the general state of the patient's health. At times morphine or other strong sedatives may be the treatment of choice. For the relief from pain confined to the inferior or superior maxillary nerves an injection of alcohol into the peripheral branch may be indicated. Obviously, the operative relief from pain is intended only for a selected group of patients whose general condition and expectancy of life is such as to make it seem advisable.

Since the tongue and pharynx are supplied by two sensory nerves, the glossopharyngeal and the trigeminus, chronic lesions frequently overlap from the domain of one nerve into the other. Under such conditions, the exclusion of only one nerve will have little effect on the intensity of the pain. Both nerves must be divided to give relief.

The trigeminal nerve supplies all of the inner side of the mouth, most of the roof and the floor of the mouth, the anterior two thirds of the tongue and the nasal sinuses. The glossopharyngeal nerve supplies sensation to the posterior third of the tongue, the uvula and the posterior part of the soft palate, the posterior wall of the pharynx and the posterior surface of the epiglottis. Pain is always greatly intensified in ulcerations of the mouth and pharynx because of the passage of liquids and food over the exposed nerve endings. The pain may also be much increased by applications of radium.

The proposal, therefore, for the relief from pain (in selected cases) when the sensory fibers of both nerves are involved or will later probably be involved is the intracranial division of both the fifth and the ninth nerves. Since the intracranial positions of the trigeminal and

* From the Johns Hopkins Hospital and University.

1. Dandy, W. E.: Section of the Sensory Root of the Trigeminal Nerve at the Pons.—Preliminary Report of the Operative Procedure, *Bull. Johns Hopkins Hosp.* 36:2, 1925; Glossopharyngeal Neuralgia (Tic Douloureux), *Arch. Surg.* 15:198 (Aug.) 1927.

glossopharyngeal nerves are in such close proximity, precisely the same approach (subcerebellar) has been used in each procedure. It is possible to divide both nerves at the brain stem almost as easily as either. The sensory root of the trigeminal nerve can be severed with much greater ease and with far less time by this new procedure, which has been used exclusively for the past two years at the Johns Hopkins Hospital and University, than by the older approach along the floor of the temporal fossa (Hartley-Krause). After a small unilateral bony defect has been made, only a few minutes are required to divide the sensory root of the fifth nerve either entirely or in part, and only a few additional seconds are needed to resect the glossopharyngeal trunk. Other great advantages of this route for section of the trigeminus are (1) the constant absence of injury of the motor branch of this nerve and (2) the almost complete absence of corneal redness and ulceration—the two principal deterrent features of the Hartley-Krause method. (3) For reasons not yet definitely ascertained, some sensation to the face is usually but not always retained.

REPORT OF A CASE

A *sallow, undernourished man, aged 40, was suffering terrific pain in the region of an old ulcer on the right side of the tongue; the pain radiated to the back of the throat, the right ear, the lips and teeth on the right side, the inside of the cheek and the right half of the hard palate. The pain was present almost constantly, and though always severe, the intensity varied from time to time. Exacerbations of the pains always resulted from rubbing the mustache and shaving or lightly rubbing the lower part of the face on the right side. The inside of his mouth burned like fire on the right side. Chewing and swallowing so greatly increased the pain in the mouth and ear that he was afraid to eat or drink. The pain was not relieved by any sedative. It was finally necessary to resort to morphine, and many strong doses were required to bring relief. During the three weeks before operative relief was obtained, it had been necessary to give 130 doses of morphine. The patient became desperate and belligerent until the large amounts of morphine reduced the pain to a point of toleration. Most of the right half of the tongue had been removed several months previously for a chronic ulcer, presumably carcinomatous. A few weeks later, the glands of the neck were removed on the right side. Microscopic sections, however, failed to show carcinoma, either in the ulcer of the tongue or in the glands of the neck. Since the ulcer followed in the wake of a healing Vincent's angina, it is more probable that the original ulcer was benign. Six weeks after the operation on the tongue, radium needles were implanted, and thereafter the pain became violent and unrelenting. On the lateral border of the tongue was a contracture due to the healed lesion. It was covered with epithelium and was not indurated. Actual ulceration was not now visible.*

Operation.—Sept. 18, 1927: A unilateral cerebellar exposure was made on the right side. The bony defect extended to the mastoid cells, which, however, were carefully avoided. The cisterna magna was punctured, releasing a large amount of fluid and thereby affording ample room for a subcerebellar exposure. The cerebellum was lifted with a spatula until the cisterna lateralis was brought into view. After evacuation of the fluid of the lateral cistern, one could at once

see the series of cranial nerves on this side. The ninth and the fifth nerves were easily isolated and divided, the former with scissors, the latter with a tiny knife at right angles to a long flexible shaft. The division of both nerves after their exposure probably did not consume more than five minutes, the entire operation taking about forty minutes.

The postoperative course was uneventful. The patient was immediately relieved from all pain, and despite the large doses of morphine which had been given before operation, there has been no further need or desire for the drug. His color, general appearance, weight and behavior rapidly improved. At the time this report was written (Feb. 1, 1928) the patient was back at work and in perfect health. He has gained 30 pounds (30.6 Kg.) in weight, and has been entirely free from all pain since the operation.

Fig. 1.—Operative approach to the fifth and the ninth nerves at the brain stem.

AFTER-EFFECTS OF OPERATION

The after-effects of the operation are confined to the loss of sensation incident to the loss of the two sensory nerves. However, in not one of three patients in whom the glossopharyngeal nerve alone was divided has there been any appreciation of this sensory loss, nor has the loss of taste over the posterior third of the tongue been noticed, although the objective sensory loss was absolute. Loss of sensation over the trigeminal area is only partial as obtained in seven of ten cases after division of the sensory root at the pons. The sensation over the forehead is only a little impaired; that over the second branch is somewhat more affected, and over the third branch, the loss is a little more.

Touch is preserved over all branches, but most acutely over the first branch. Heat and cold can be differentiated over all branches, but most keenly over the first branch. The corneal reflex is retained. This seeming paradox, i. e., preservation of sensation, is the usual story and greatly reduces the subjective feeling of great numbness which obtained after the old operation. It is not due to partial severance of the nerve as might be suspected. Perhaps there are sensory fibers accompanying the motor branch of the nerve which is always preserved intact.

INDICATIONS FOR AND ADVANTAGES OF THE OPERATION

When the sensory domain of the glossopharyngeal nerve is invaded by carcinoma or a chronic or incurable lesion, relief can be obtained only through section of the ninth nerve.² Alcoholic injections of the

Fig. 2.—Scar of patient whose fifth and ninth nerves were divided intracranially. The photograph was taken ten days after operation.

nerve are practically precluded because of the intimate relations between the peripheral fibers of the vagus, and also because of the fact that the glossopharyngeal nerve lies in the sheath of the jugular vein and close to the internal carotid artery. Peripheral section of the glossopharyngeal nerve in the neck is much more dangerous than intracranial section of the nerve because of the intimate association with the vagus nerve,

2. T. Fay recently divided the ninth nerve intracranially and the upper three spinal sensory roots by a combined laminectomy and cerebellar exposure. He thought it necessary to divide this group of nerves because the more distant skin areas of the neck had been invaded by an ulcerating carcinoma which was primary in the neck (*Intracranial Division of the Glossopharyngeal Nerve Combined with Cervical Rhizotomy for Pain in Inoperable Carcinoma of the Throat*, *Ann. Surg.* 84:456, 1926.)

injury to which induces profound disturbance of deglutition. The vagus has always been injured when section or avulsion of the glossopharyngeal nerve has been attempted in the neck. Moreover, intracranial section of the central fibers of the ninth nerve makes their regrowth impossible, whereas after peripheral division, the pain would doubtless return. Intracranial section is easier and almost devoid of danger.

Should the domain of the trigeminal nerve alone be involved, and the involvement be only on one side, the relief from pain offers the choice of two methods, (1) injection of alcohol and (2) intracranial section (either partial or total) of the sensory root of the trigeminus. If the lesion is a carcinoma and so rapid in its growth that the duration of life is probably a matter of few months, the injection of alcohol into the inferior or superior maxillary branches of the trigeminus would be preferable.

However, should the probable duration of life be many months or years, or should the lesion be such that the duration of life is not directly affected, division of the trigeminal nerve intracranially by the cerebellar route is far superior to the repeated and painful injections with the added loss of the muscles of mastication.

But when with the same expectancy of life the lesion is such that the sensory domains of both the ninth and the fifth nerves are involved, injections of alcohol will be futile. Intracranial section of the ninth nerve alone will give relief in its distribution; and, as previously noted, when this is done the sensory branch of the fifth nerve is already in view and can be easily divided. It need not be emphasized that when the sensory root of the fifth nerve is divided through the temporal route (Hartley-Krause operation) it is not possible to section the glossopharyngeal nerve at the same time, for it is far afield of this exposure. Moreover, there is far less hesitancy in advising division of the sensory branch of the trigeminal nerve by the cerebellar route than by the temporal approach since trophic disturbances of the eye are eliminated and injury to the motor branch of the trigeminal nerve (muscles of mastication) never occurs; finally, the operation has not been attended with mortality.

There remain the possibilities of relieving pain when the lesion is in the midline of the tongue, mouth or pharynx, and involves the sensory fibers of both trigeminal, or of both ninth, or even perhaps of all four nerves. The cerebellar approach to the intracranial part of these nerves is easily extended to a bilateral exposure by enlarging the unilateral into the bilateral approach which is more or less routine in operations for cerebellar tumors. Whether both glossopharyngeal and both trigeminal nerves could be sacrificed, one can only infer. In a case of bilateral trigeminal neuralgia, the sensory roots of both trigeminal nerves have

been divided by this approach at one sitting and with no added operative difficulties other than the greater time consumed in making a bilateral instead of a unilateral cerebellar exposure. The additional division of both ninth nerves, while not difficult technically, might well be impracticable because of the loss of the gag reflex.

Whether chronic lesions of the tongue or nasopharynx would ever present the need of such operative relief, I am not prepared to say. In such cases, bilateral alcoholic injections of the inferior maxillary nerve would be precluded because both motor branches of the trigeminus would be paralyzed and swallowing made impossible. Relief from such pain could hardly be obtained safely except by section of the sensory roots at the pons where the motor roots are safely removed.

Whether both glossopharyngeal nerves could be divided for the relief from pain cannot be answered by precedent. Though technically easy and safe, the absence of the gag reflex on both sides would probably make it impractical. Division of either the ninth or the fifth nerve, or of both on one side, may also be of advantage in permitting the application of radium to a malignant lesion without pain, immediately or subsequently.

SUMMARY AND CONCLUSIONS

An operation is presented for the complete and permanent relief from pain associated with chronic, benign and malignant lesions of the mouth, nose, tongue and throat. When the pain is referable to the sensory domain of both the glossopharyngeal and trigeminal nerves on one side, there is no other way of permanent relief. Under such conditions the glossopharyngeal nerve and the sensory root of the trigeminus can be divided at the brain stem (subcerebellar approach), both nerves being exposed simultaneously in the same operative field. Both nerves can be divided easily, quickly and with little danger to life or function.

NOTE: Since this article was sent for publication, three additional cases of combined fifth and ninth nerve divisions have been performed. In two of the patients the upper three cervical sensory roots have also been divided intradurally because the malignant lesions had extended into the domain of the cervical nerves.

BRONCHOBILIARY FISTULA *

M. G. SEELIG, M.D.

AND

J. J. SINGER, M.D.

ST. LOUIS

During September, 1927, we saw a patient in whom a bronchobiliary fistula developed. The infrequency of this type of lesion prompted us to collect and analyze the literature on bronchobiliary fistulas. We had just instituted our studies when the admirable article by Morton and Phillips¹ appeared, making it not only unnecessary but even unwise to publish another detailed report. In the paper by Morton and Phillips will be found everything pertaining to the history, etiology, pathologic characteristics, symptomatology, prognosis and treatment of bronchobiliary fistula. However, it may be worth while, in a condition so unusual, to submit a report of the case of our patient merely as a matter of record.

REPORT OF A CASE

L. R., an obese, white, married multipara, aged 39, was operated on for appendicitis by one of our colleagues in St. Louis, in the hope of relieving headache, constipation, nausea and pain in the lower right quadrant. The appendix was found to be inoffensive, and exploration of the abdomen yielded no positive information. She was discharged on Sept. 27, 1921, feeling very well. Six weeks later, pain developed in the upper right quadrant, radiating to the back, and was accompanied by nausea and vomiting; the pain occurred in attacks, but was unaccompanied by jaundice or febrile symptoms. Her surgeon decided that the symptoms warranted a direct exposure of the gallbladder. The gallbladder, containing three stones, was small, and bound down to the liver and the duodenum so firmly that it was removed with much technical difficulty. The cystic duct was clamped, and the clamp was left in situ for several days. Six days after the operation, a biliary fistula established itself, and when the patient was discharged from the hospital, eight weeks after operation (April 12, 1924), there was a free discharge of bile from an abdominal fistula in the operative scar.

Six months later, the patient was readmitted to the hospital, complaining of prostration, nausea without vomiting, universal pruritus and persistent diarrhea. She was deeply jaundiced, the stools were clay-colored, showing no trace of bile, and the biliary fistula discharged profusely. At that time, pain was a negligible factor. Her surgeon, suspecting that he had overlooked a stone of the common duct, attempted to locate and remove it; however, owing to dense adhesions and the poor physical condition of the patient, he was unable to locate the duct. After this operation, the patient was seen by Dr. Evarts Graham, who expressed the opinion that there was an obstruction of the common duct, the nature of which

* Submitted for publication, Feb. 2, 1929.

1. Morton, J. J., and Phillips, E. W.: Bronchobiliary Fistula, Arch. Surg. 16:697 (March) 1928.

was not entirely clear, but which was probably the result of an injury to the duct at the time of the former operation, with resultant stricture, and that another surgical attempt should be made to relieve her.

We concurred fully in the opinion of Graham, and on Nov. 25, 1925, an operation was performed. This operation, which was technically difficult owing to the obliteration of all landmarks due to dense adhesion and the absence of the gallbladder, disclosed that the lower portion of the common duct was missing. Between the stump of the duct and the duodenum there was a gap of $1\frac{1}{2}$ inches (3.77 cm.). The duodenum was mobilized, and a small catheter was fixed in the end of the common duct which led into the lumen of the duodenum through a puncture of its superior wall; the duodenum and common duct were then approximated so that they just touched. Sutures held these two structures in loose apposition, and omentum was wrapped around the site of the anastomosis. Following the operation, the stools became colored, the discharge of bile through the fistula ceased, the jaundice cleared up and the patient rapidly returned to a normal condition. The catheter was passed by rectum on the twenty-fourth postoperative day, and the patient left the hospital in excellent condition a month after the operation.

Ten months later, on Sept. 24, 1927, the patient was readmitted to the hospital. She said that she had not felt normal since the last operation; however, she was able to do her work and was not compromised by any definite symptoms pointing to the biliary tract until eight months after operation, at which time she had an attack of nausea and vomiting which lasted three days. Jaundice was not present, though she was almost constantly plagued by pruritus. She did not consult a physician, in spite of the fact that the attacks of nausea and vomiting were repeated at frequent intervals. Finally, after a month of the illness and three days before admission to the hospital, she had a violent attack of pain in the right upper quadrant.

Symptoms and signs at that time were as follows: deep jaundice, yellow sclerae; pale gray stools; highly colored (bile) urine; constant and severe general pruritus with dermatitis from scratching (till blood flowed); acute pain in the region of the liver referred to the back and right shoulder; nausea and vomiting; a temperature of 102 or 103 F., and chills. Physical examination disclosed evidence of compression of the lower lobe of the right lung. Fluoroscopy and roentgenograms showed a high fixed diaphragm on the right side, a normal upper lobe of the right lung with a compensatory air content in the left lung. The white blood count ranged from 13,000 to 22,000.

The history and the previous operations, symptoms and physical signs all pointed to an obstruction of the bile passages complicated by subphrenic abscess or pneumonia of the lower lobe of the right lung. An exploratory operation was decided on, but the condition of the patient was grave, and it was decided to wait a few days. On September 27, definite bronchial breathing with increasing dulness in the lower lobe of the right lung indicated pneumonia. Under these circumstances, operation was postponed. When a roentgen examination was made at that time, we found evidence of a dense shadow in the lower lobe of the right lung extending up to the fourth rib anteriorly. A diagnostic pleural puncture was made, but no fluid was found.

The usual expectant treatment for pneumonia was instituted. On September 30, the patient coughed up lemon-colored sputum which had a bitter taste. The Gmelin test showed the presence of bile. For the next few days, the patient raised considerable purulent sputum heavily stained with bile. The jaundice cleared rapidly with the discharge of the bile through the bronchobiliary fistula

On Oct. 5, 1927, an attempt was made to outline the bronchobiliary fistula by the introduction of iodized oil into the bronchial tree. Unfortunately, we were unsuccessful in this procedure. The patient improved gradually, and the signs of the pneumonic condition of the lobe of the right lung diminished. The patient was discharged from the hospital on October 22, much improved. At the time of writing, one year later, she showed recurrent attacks of jaundice, but neither pain nor cough.

COMMENT

Bronchobiliary fistula is unusual, and in this case was not considered a possibility until bile appeared in the sputum. At the time of the illness (Sept. 9, 1927), it was thought that the fever, chills and signs of septic pneumonia were secondary to a subphrenic accumulation of bile and pus. One occasionally sees bile leakage accumulate either in the subphrenic space or in a dead space about the cystic duct. This fluid frequently gives rise to considerable pain and to jaundice until the pocket is opened. It is most probable that the dilatation of intrahepatic biliary passages occurred, with secondary inflammation, leading to abscess formation and perforation into the subphrenic space. Later, the subphrenic abscess perforated the diaphragm, establishing a bimuicous fistula between the bronchial tree and the intrahepatic bile capillaries and ducts through the intermediate agency of a suppurative pneumonitis. Prompt relief from symptoms followed the expulsion of bile and pus through the bronchial tree. It would have been instructive to have obtained a picture of the two connecting cavities of lung and liver with iodized oil, but the attempt to introduce the oil through the lung was unsuccessful. A study of the literature shows that this procedure was attempted by Oltiker,² with negative results. A study of the roentgenograms showed clearly the pulmonary lesion at the time of the acute symptoms and the clearing up of the pneumonic shadow after the bile was expelled.

ENDOMETRIOMA OF THE TERMINAL ILEUM, APPENDIX AND CECUM *

F. N. G. STARR, C.B.E., M.B.

TORONTO

Since Sampson's¹ exhaustive article on perforative hemorrhagic (chocolate) cysts of the ovary, one finds from time to time many and varied evidences of endometriosis. I have seen several such cases² in which the appearance of the uterus closely resembles a leiomyoma, but in which there are many firm dense adhesions to the ovaries, pelvic wall, rectum and sigmoid. In these cases, when trying to arrive at a definite diagnosis, there has always been one definite symptom of which all the patients have complained, pain in the rectum preceding and often accompanying defecation.

The case I shall describe is, I think, unique in that there has never been any menstrual disturbance, and the patient has always been considered a strong, healthy member of her sex.

REPORT OF A CASE

Dr. Donald MacGillivray asked me to see a maiden lady, aged 38, on the evening of March 16, 1927. The history was that for several days she had experienced some discomfort in the right side of the abdomen, which had become more pronounced during the previous night. There had been some constipation, and associated with this there was some nausea but no vomiting. On examination tenderness was found in the right iliac fossa, a comparative rigidity only, but at times a mass could be felt. When this was palpated, a peristaltic wave was observed to extend to the mass. There was evidence of free fluid in the peritoneal cavity. I took this to mean a slowly leaking appendicitis, around which omentum had become lapped, and as the inflammatory reaction increased a partial obstruction had developed. The leukocyte count was 14,000.

When the abdomen was opened, a considerable amount of turbid serum was evacuated. When the cecum was brought into the wound, accompanied by the terminal ileum, no appendix could be seen, nor was there any omentum around the mass. A careful inspection was made to ascertain if the appendix was buried in the posterior wall of the cecum, but none could be found. Because of the almost complete obstruction, a resection was decided on. The terminal ileum about 6 inches (15.24 cm.) from the ileocecal valve, the cecum and part of the ascending colon were removed, and an end-to-end anastomosis was done over the rubber tube.³ The convalescence was uneventful, the tube being passed per rectum on the seventh day. The patient has continued in perfect health.

* Submitted for publication, Feb. 11, 1929.

3. Starr, F. N. G.: Tr. Am. Surg. Soc. **40**:260, 1922.

The pathologist, Dr. W. L. Robinson, reported as follows: The gross specimen consisted of a portion of bowel, measuring 15.5 cm. in length. Its lumen was narrowed by a thickening which involved about two thirds of the circumference of the bowel for a distance of about 2.5 cm. at its longitudinal axis. On one side of the constriction, the wall of the bowel showed a greater circumference than that on the other side. The thickening caused a partial obstruction of the bowel. The lumen barely admitted the finger tip. The cut surface of the bowel was an opaque creamy white and was fibrous. Its margin was indistinct. On microscopic examination, the thickened wall of the bowel was seen. The muscle fibers were hypertrophied, and the fibrous connective tissue of the subserosa was increased in amount. The subserous and the muscle coat, almost up to the mucosa, were invaded by glands typical of endometrium along with stroma precisely like that of endometrium. Some of the glands were large and contained red blood cells and epithelial cells with hemosiderin. There was no inflammatory infiltration and no evidence of malignancy. The appendix as such was not recognized, probably being drawn up into the fibrous tumor mass.

The diagnosis was endometriosis.

The extraordinary feature of this case is that apparently the uterus and adnexa were normal and there was no sign of a chocolate cyst of the ovary. The inference, of course, is that at some time the appendix had been in contact with the fimbria and thus some endometrial cells had come in contact. Possibly it may have become adherent and as the obstruction increased and peristalsis became more vigorous, it was detached, although there was no sign of a recent adhesion on the part removed; however, her first discomfort a few days previously may have been caused in this way.

MISCELLANEOUS

The Adult Cripple.—O'Reilly,⁴⁹ in his chairman's address before the Section on Orthopedic Surgery of the American Medical Association, selected for his theme the problem of the adult cripple, and pointed out the all important rôle of orthopedic surgery in helping him to attain economic independence. He urged all orthopedic surgeons to bend their efforts toward improving the standards of treatment and providing better and increased institutional facilities. In order to secure the greatest degree of vocational rehabilitation, it was necessary to obtain the maximum physical rehabilitation. Not only humanitarian motives but economic principles justified the establishment of adequate hospitals manned by expert staffs devoted to the treatment of the adult cripple.

[ED. NOTE.—We believe that O'Reilly has called attention to one of the greatest needs in caring for the sick. Adequate provision in the way of hospital care has been made for the acutely ill patient, and a good beginning has also been made in providing facilities for the treatment of crippled children. The problem that is as yet almost untouched is that of the adult patient with chronic disease. With proper institutional facilities, the wage earning ability of many of these could be restored,

49. O'Reilly, Archer: *Adult Cripple*, J. A. M. A. **91**:137 (July 21) 1928.

and this would relieve society not only of the burden of their care, but of that of providing for those dependent on them.]

Osteochondritis Dissecans.—Reporting on a study of patients with osteochondritis dissecans, Geyman⁵⁰ pointed out that the condition was found chiefly in young adults, and that the sites most commonly involved were the medial condyle of the femur and the external condyle of the humerus. Of the various theories that have been put forward to explain the origin of the disease, he thought that trauma was the most likely cause.

Wolbach and Allison⁵¹ obtained the entire knee joint of a patient who had osteochondritis dissecans, and were able to make a thorough study not only of the loose fragment, but of the bed from which the fragment came and also of the underlying bone. They found that the fragment had been produced by a fracture into a cystlike cavity that had developed in the underlying bone. That the cystic degeneration found in this specimen accounted for all cases of osteochondritis dissecans was not claimed, but it probably offered an explanation of certain cases.

Damage to Bone Growth Resulting from Exposure to Roentgen Rays.—Beck⁵² made a report of six patients in whom a marked limitation of bone growth was noted after repeated exposure to roentgen rays for the treatment of tuberculosis. The treatment had been given from five to fourteen years previously at a time when roentgen treatment was employed in heavy doses. In one patient, the shortening amounted to 15 cm. The writer was inclined to the view that all of the cells of the epiphyseal region rather than only cells of specialized function were damaged. He based this opinion on the general changes noted in the roentgenograms.

[ED. NOTE.—Beck's observations are important, if correct, but one would wish to be certain that the shortening resulted from the roentgen treatment rather than from the disease process itself.]

Osteomyelitis Due to Monilia.—Connor⁵³ described a case of osteomyelitis which was apparently caused by infection with *Monilia* (a type of yeast organism). The patient was a girl, aged 19, who entered the hospital with several draining sinuses located above the elbow. Later, an abscess developed over the buttock, and was found to connect with a focus of osteomyelitis in the ilium. There was no fever and no leukocytosis. An organism was recovered from the pus which was identified as *Monilia psyllosis*.

The Functional Importance of Equalization of the Length of the Legs.—That equalization of the length of the legs when one leg was shorter than the other was of great importance for the functional development of the shorter leg, especially in cases of paralysis and other conditions, was stated by Deutschlaender.⁵⁴ The shorter leg was always weaker and more easily fatigued, and rendered the gait uncertain. Raising the sole of the shoe was never a satisfactory means of solution, because it never increased the locomotor power, although it did improve the equilibrium. The writer preferred to shorten the longer leg; sometimes it was necessary to shorten it in more than one place. He had performed the operation of shortening the bone in seventy patients, and had been entirely satisfied with the results. The operation had resulted in making the legs of almost equal length and in greatly improving the gait. All of the patients were enabled to wear ordinary shoes.

[ED. NOTE.—The question to determine here is whether it is better policy to equalize the length of the legs by shortening the long, or normal leg, or by lengthening the short leg. Until recently, the results of the procedure of lengthening the bone were uncertain, but substantial progress has been made by Abbot in the use of an improved method described in a previous "Report of Progress in Orthopedic Surgery."⁵⁵ As familiarity with this technic is acquired, we believe that it will be preferred to the operation of shortening the bone.]

Spontaneous Dislocation and Destruction of the Tendon of the Biceps Brachii.—From studies of the shoulder joint in cadavers, Meyer⁵⁶ concluded that spontaneous partial or complete forward dislocation of the portion of the biceps tendon lying between the tuberosities of the humerus was not an uncommon occurrence. It probably occurred most frequently in laborers past middle age. Division of the tendon in this portion might occur as the result of degenerative changes and of the process of wear and tear, but usually the tendon reattached itself to the humeral shaft just beyond the lesser tuberosity. If this reattachment did not occur, a marked atrophy of the lateral belly of the biceps muscle resulted.

Traumatic Osteoporosis of the Carpal Bones.—Buchman⁵⁷ discussed osteoporosis of the carpal bones (Kienböck's disease; Preiser's disease) in respect to etiology, pathology and treatment. He believed with Leriche that in this disease there was a disturbance of vasomotor

equilibrium; that a fracture frequently accompanied, but was not essential to, the process; that absorption began regardless of whether a fracture was present or not, and that fracture and extensive destruction occurred as a result of the atrophy. Conservative treatment in the form of immobilization in the "cock up" position should be tried for a reasonable length of time, but if disability persists, then the involved bones should be excised. In the hands of the author, the operative treatment had given good results.

He reported seven cases; in three, the process involved only the scaphoid; in the fourth the scaphoid and semilunar; in the fifth the scaphoid, semilunar and os magnum; in the sixth the semilunar, os magnum, and unciform, while in the seventh the os magnum and unciform were affected.

[ED. NOTE.—Traumatic osteoporosis is a most baffling condition and sometimes defies all treatment. Its cause is obscure, but the general tendency is to regard it as a trophoneurosis. All surgeons who have had first hand acquaintance with the lesion will welcome any new light that may be shed on it.]

Stenosing Fibrous Tendovaginitis Over the Radial Styloid.—Since de Quervain's original description of stenosing fibrous tendovaginitis over the radial styloid, Schneider⁵⁸ found that 144 cases illustrating the condition had been reported. It was caused by excessively monotonous motions of the thumb in abduction and extension, these leading to a thickening of the tendon sheaths of the abductor pollicis longus and the extensor pollicis brevis as they passed over the radial styloid. It occurred more often in women.

In most of the patients relief was to be obtained by complete immobilization with the thumb in a position of abduction and extension over a period of from six to eight weeks. In a few obstinate cases, it was necessary to expose the seat of the trouble by an incision and to split the tendon sheath.

SURGICAL PROCEDURES ON THE BONES, JOINTS AND TENDONS

Spinal Fusion with Osteoperiosteal Graft.—Allison⁵⁹ described the technic of spinal fusion with the aid of the osteoperiosteal graft which had been employed at the Massachusetts General Hospital for a number of years. The operation consisted essentially of the Hibbs procedure with the addition of a thin osteoperiosteal graft in the shape of a long flexible ribbon which was removed from the anteromedial surface of the tibia and laid down on the surface of bone chips and fragments pro-

⁵⁸ Schneider, Chester C.: Surg. Gynec. Obst. 46:846 (June) 1928.

⁵⁹ Allison, Nathaniel: Surg. Gynec. Obst. 46:826 (June) 1928.

duced by the spinal operation. In the author's opinion, the addition of this osteogenetic material served to stimulate the production of a greater amount of new bone than would otherwise be obtained and hence represented an additional guarantee of a successful outcome. The graft was always removed by a second operating team and hence did not prolong the time of the operation or add to the shock.

Enlargement of Parturient Canal by Bone Graft.—Albee⁶⁰ reported that in two patients with contracted pelves he had successfully enlarged the pelvic outlet to permit childbirth. The technic consisted of inserting at the symphysis pubis a bone graft 1½ inches (3.7 cm.) long which was removed from the tibia.

[ED. NOTE.—While concerning chiefly the sister specialty of obstetrics, this procedure ought to be of much interest to orthopedic surgeons, particularly as it affects the mechanics and function of the sacro-iliac joints.]

Transtrochanteric Approach to the External Iliac Fossa in Osteoplastic Operations.—For certain operations on the hip, such as the shelf operation in congenital dislocations, the procedure of arthrodesis and bone grafting in ununited fractures, Calvé⁶¹ described a new T-shaped incision. The long vertical limb of the incision was made to extend from the base of the lateral surface of the greater trochanter to the iliac crest at the junction of the anterior third with the posterior two-thirds. From the summit of this incision two shorter cross incisions were made, one extending anteriorly and the other posteriorly following the curve of the iliac crest. The deeper tissues were then separated, exposing the greater trochanter but without dividing the muscles attached to the latter. The edges of the gluteus medius and gluteus minimus were then defined and separated. Proceeding carefully at this point, the operator exposed the arterial and venous branches of the gluteal vessels; these branches were then clamped and cut between ligatures. The greater trochanter was next sectioned by a vertical incision extending from its summit for a distance of from 1 to 2 cm., at which point it separated into two oblique incisions, the anterior one running forward and outward, the posterior one running backward and inward. The two fragments of the trochanter were then retracted without being completely separated from their femoral attachments. One thus obtained a wide exposure of the capsule of the joint, the acetabular margin and the external surface of the ilium.

[ED. NOTE: It is difficult to see how injury to the nerve supply of the tensor fasciae femoris muscle could be avoided by this incision.]

60. Albee, F. H.: Surg. Gynec. Obst. **46**:845 (June) 1928.

61. Calvé, Jacques: Presse méd. **36**:695 (June 2) 1928.

Arthroplasty of the Knee.—Campbell⁶² discussed the results of arthroplasty of the knee, basing his remarks on a study of 111 patients. He employed an operation which remodeled the lower end of the femur in the form of a single condyle extending across the transverse diameter of the bone, this articulating with a concavity in the upper surface of the tibia. Fascia was interposed between the ends of the bones. In forty-three of 111 patients whom he was able to follow, a useful range of motion resulted, varying in extent from 35 to 120 degrees. As experience with the operation increased, a betterment of the functional results was noted. The indications, contraindications and postoperative treatment were thoroughly discussed.

Albee⁶³ described how his own conservative attitude of ten years ago concerning arthroplasty for bony ankylosis of the knee had changed to one of moderate enthusiasm because of ten successful results he had obtained by operation since 1920. He analyzed these cases, calling attention to the technical features which had contributed to the favorable outcome. He believed that the technic of wedge-shaped arthroplasty with the reconstructed convex femur fitting into the concave tibia maintained mobility and at the same time prevented lateral instability. For interposition, he employed fascia which was covered with a layer of fat. He did not believe that old healed tuberculosis of the knee was necessarily a contraindication to arthroplasty.

[ED. NOTE.—The increasing number of favorable reports on arthroplasty of the knee shows that in skilled hands the operation here yields better results than in the case of most of the other joints, with the exception of the elbow and the jaw.]

The Operation of Stripping the Os Calcis.—Describing the technic of his operation of stripping the os calcis for pes cavus, Steindler⁶⁴ stated that he always used the medial incision and never the incision around the heel. He emphasized the importance of thoroughly stripping the structures as far forward as the calcaneocuboid joint. In addition to the stripping of the os calcis, wrenching of the foot or some other operation on the bones often was necessary to restore and maintain the balance of the foot. An analysis of the results obtained in 201 patients who had been followed for a number of years was presented.

A Conservative Operation for Bunions.—McBride⁶⁵ described an operation for the correction of hallux valgus which he had employed in a large number of cases. The operation consisted of transplanting the conjoined tendons of the adductor muscle group of the great toe to

the dorsum of the head of the first metatarsal bone. The bursa was also dissected out and the bony prominence chiseled away. After the capsule was repaired and the wound closed, a light plaster casing was applied. McBride permitted weight bearing at the end of two weeks.

FRACTURES

Fractures in Industry.—From an analysis of the experience with several thousand fractures covering a period of twelve years, Davis⁶⁶ found that it was possible in simple uncomplicated fracture to predict the cost of treatment in the average case fairly accurately. The average period of time lost in this group of cases was 27.3 days. The actual cost to the injured employee was based on the average time lost and the average of the different earnings, and amounted to \$6.00. The actual cost to the employer was \$20.97 a week when the patient was not hospitalized and included the cost of taking care of the fracture plus compensation. When the patients were hospitalized, their sustenance had to be added, and this amounted to \$31.78 a week. When the patients were sent to a private hospital, the cost was much greater and included the minimal ward rate of \$3.50 a day, the laboratory fee and the cost of materials, the professional charge of the physician and compensation to the employee. The figures indicated that the percentage of disability could be reduced by skilful operative procedures and careful postoperative treatment. In many instances the period of disability was prolonged, and the cost both to himself and to his employer was increased by the poor physical condition of the patient.

Bone Repair and the Healing of Fractures.—Cowan⁶⁷ produced simple fractures in the bones of kittens and studied the reparative processes grossly, microscopically and roentgenologically at intervals varying from twelve hours to thirty-four days. He concluded that the periosteum was more essential in healing than the medullary tissue or cortical bone. Fibrous union or pseudarthrosis was more apt to develop following extensive destruction of periosteum at the fracture line or after wide separation of the fragments. If after fibrous union was established, weight bearing was permitted, a false joint often developed at the fracture site. To overcome this, it was necessary to excise the fibrous and cartilaginous tissue.

Mock⁶⁸ was of the same opinion as Cowan and cited clinical and experimental evidence to substantiate his claim that of all the elements of bone, the periosteum was the most important in bone repair. In delayed union or loss of bone substance, he would practically always use

67. Cowan, John: *Ann. Surg.* **88**:749 (Oct.) 1928.

68. Mock, H. E.: *Surg. Gynec. Obst.* **46**:641 (May) 1928.

the periosteal graft or if the defect were too great he would prefer an osteoperiosteal strip.

In experiments on kittens, Glaessner and Hass⁶⁹ found that thymectomy delayed the formation of callus, and that injection of an extract of thymus hastened bone consolidation. In a series of experiments on older cats, the influence of extracts of various endocrine glands was tested. Thymus extract was found to be the most potent in its effect on formation of callus. The next most potent extract was that of the parathyroids. These authors had employed the extract in a considerable number of patients with delayed callus formation and had noted beneficial results.

Fine and Brown⁷⁰ performed some experiments on dogs to study bone repair under the influence of parathyroid extract-Collip. They concluded that the experiments, although small in number, showed that the parathyroid extract delayed the speed of deposition of calcium in regenerating bone in young dogs, whereas in adult dogs no clear evidence as to its potency in this or in the reverse direction was obtained. In their opinion the practical significance of these observations was that the clinical use of the parathyroid extract for delayed bone union was not based on any sound principle, could do little if any good and, in fact, might do harm.

Robinson⁷¹ made a study of the rôle of the circulation in the healing of fractures and came to the conclusion that an inadequate blood supply was one of the most important factors contributing to delay and failure of bone repair. He emphasized the necessity of an adequate supply of new blood vessels for the deposition of lime salts in the callus. He pointed out the importance of making provision for expansion of the surrounding soft structures in the treatment for fractures, of avoiding compression by tight bandages, and of splitting circular plaster casing on two sides.

Fracture and Dislocation of the Sternum.—Three instances of fracture or dislocation of the sternum were reported by Holderman.⁷² From a statistical review, he found that this type of fracture represented considerably less than 1 per cent of all fractures. It was usually produced by a direct blow, but might also result from indirect violence. The commonest site of separation of fragments was at the junction of the manubrium and gladiolus. In most instances the dislocation could be satisfactorily reduced by closed methods, but open operation was often justified.

Fracture of the Clavicle.—Funston⁷³ described a splint for the treatment of fractures of the clavicle. It was based on the principles of the clavicular cross, but did away with the mechanical objections to it of bulkiness and of pressure against the vessels and nerves in the axilla as well as the loss of tension when the dressings had loosened. The splint was made of steel rods about $\frac{1}{4}$ inch in diameter and was furnished with special pressure drums covered with felt which exerted a strong pressure on the front of the heads of the humeri in a backward direction. Steel rods passed backward from these, arching under the axillae without making any pressure and terminated in two pressure pads pressing against the back in the interscapular region. These were connected with a vertical member of the brace which extended down the back for the purpose of exerting leverage, its end being held in place by a circular strap about the pelvis.

Yates and Guest⁷⁴ recorded an unusual complication of fracture of the clavicle. A woman, aged 41, died of cerebral embolism due to thrombosis of the subclavian artery which had been caused by pressure of an ununited fracture of the clavicle.

[ED. NOTE.—Funston's splint is ingenious and ought to be effective. Unfortunately, the services of an experienced brace fitter and a considerable amount of time are required for its manufacture.]

Vertebral Fractures.—Wilmoth⁷⁵ presented the case histories of seventeen patients who had fractures of the transverse processes or chip fractures of the lumbar vertebrae. He was of the opinion that such injuries were of relatively frequent occurrence and were due to forcible hyperextension of the spine or to sudden muscular action. The trauma was usually slight, and this led to incorrect diagnosis as the injury did not seem sufficient to justify roentgen examination. As far as treatment was concerned, it ought to be the same in chip fractures as in other types of fracture, namely, rest and immobilization.

[ED. NOTE.—The chief feature of interest in this article is the suggestion that hyperextension of the spine may cause a chip fracture of the spine as well as hyperflexion. The observation needs to be confirmed.]

Kümmell's Disease.—In a thorough article reviewing the literature and what is known of the pathology, Cardis, Walker and Oliver⁷⁶ reported fourteen cases of Kümmell's disease. They were able to study the lesion in a patient who died from an intercurrent disease. Examina-

76. Cardis, J.; Walker, G. F., and Oliver, R. H.: Brit. J. Surg. **15**:616 (April) 1928.

tion of the specimen showed no signs of injury of the spinal cord, no evidence of tuberculosis or abscess, no bone necrosis and the absence of pathologic changes in the intervertebral disk. The second lumbar vertebra was wedge-shaped. The margins of the bone were intact, except for a small fracture in the upper anterior part. The spongiosa showed multiple small hemorrhages. On microscopic examination the bony framework showed marked atrophy with a changed appearance of the marrow, the cells of which were decreased in number and stained poorly.

Fractures of the Pelvis.—Sever⁷⁷ made a study of fifty-one patients with fractures of the pelvis. He classified these as follows: fractures of the ilium, twelve; fractures of the pubic arch, twenty-five, and fractures involving the acetabulum, fourteen. In fractures of the ilium without lesions of the abdominal contents, treatment gave good results. Acetabular fractures were of two types: first, those which merely showed fissures in the acetabulum as well as those with slightly greater involvement, that is, where there had been a little protrusion of the inner wall or a spicule broken off from the inner table; second, those which showed protrusion of the whole acetabular wall or even a penetration of the femur into the pelvis.

In the first class, good function and little or no disability resulted. In the second class there was always some disability, often considerable, with some limitation of the motions of the hip. Treatment might modify this eventual disability somewhat. The age, occupation and habits of the patient might modify it more. There was the possibility that secondary changes might develop in the course of time and still further affect the function of the joint.

[ED. NOTE.—We have observed marked interference with function after deforming fractures of the acetabulum, especially those in which the femoral head penetrates the acetabulum. We believe that every effort should be made to correct the deformity in the early stage. The method described by Putti of two way skeletal traction would appear to offer an effective remedy.]

Dislocations and Simple Fractures of the Elbow.—Geist and Henry⁷⁸ reviewed 150 consecutive cases of simple fractures and dislocations about the elbow joint. The ages of the patients varied from 4 months to 77 years; 54 per cent of the cases occurred before the age of 16, and 20 per cent occurred between 21 and 30.

Of the dislocations, the posterior variety was the most common, constituting 6 per cent of the injuries. Backward dislocation with fracture occurred in 3.4 per cent of the patients. Internal lateral dislocation was present in 1.4 per cent of the patients. In 2 per cent a dislocation of

77. Sever, James Warren: *New England J. Med.* **199**:16 (July 5) 1928.

78. Geist, E. S., and Henry, M. O.: *Minnesota Med.* **11**:509 (Aug.) 1928.

the head of the radius occurred. There were no cases of anterior or divergent dislocation.

The fractures were divided as follows: the lower end of the humerus, 61.4 per cent; the upper end of the radius, 10.7 per cent; the upper end of the ulna 8.6 per cent; explosion fracture (shattering of all bones), 6 per cent. The ulnar nerve was injured in several of the fractures of the internal condyle. The prognosis was considered serious in fractures of the head and neck of the radius, and it was often necessary to remove the radial head. The authors advised operative suture in all cases of fracture of the olecranon with displacement. They considered the prognosis bad in all patients with shattering fractures of the lower end of the humerus. They obtained better results by conservative treatment than by operative treatment in this type of fracture. They advocated immobilization of the elbow in a position of 75 degrees flexion with early active and passive motion.

Fractures of the Upper End of the Femur.—By experiments performed on the cadaver, Shaw⁷⁹ was able to refute the contentions of Stebbing based on clinical observations that intertrochanteric fractures of the femur were due to indirect violence and that direct violence on the trochanter caused a fracture of the acetabulum, rather than an intertrochanteric fracture. Shaw was able to produce intertrochanteric fractures by the application of direct violence to the trochanter and also by outward leverage on the shaft of the femur when the head and trochanter were fixed. Axial force applied to the femur (hammering on the lower end of the shaft) did not cause an intertrochanteric fracture. He was unable to produce a fracture of the acetabulum, although increasing powerful pressure on both trochanters caused fractures of the rami of the pubis and ischium.

Skeletal Traction in the Treatment of Fractures.—Groves⁸⁰ described his technic for applying skeletal traction in the treatment for fractures. He preferred transfixion pins to nails, ice tongs or Finochietto's stirrup. He transfixed the femur above, not through, the condyles to avoid the synovial sac of the knee joint and to obtain a pull from the dense bone of the shaft rather than from the cancellous bone. For fractures of the lower third of the femur and those involving the knee joint, he transfixed the crest of the tibia just below the tubercle. He employed traction force of from 20 to 60 pounds (9 to 27 Kg.), with counter traction obtained by raising the foot of the bed 12 inches (30.5 cm.) and passing padded perineal bands round each thigh and tying them to the upper posts of the bed. In treating fractures of the tibia and fibula, he transfixed the posterior process of the os calcis as far back as possible in

79. Shaw, J. J. M.: Brit. J. Surg. 16:120 (July) 1928.

80. Groves, E. W. Hey: Brit. J. Surg. 16:149 (July) 1928.

order to counteract the pull of the tendo achillis; in fractures through the upper third of the leg bones or in fractures of the ankle with separation of the tibia and fibula, however, he preferred to transfix the malleoli. He seldom used skeletal traction in the upper limb, although occasionally he found it necessary to transfix the olecranon, using a 10 pound (4.5 Kg.) weight, in severe fractures of the humerus just above or into the elbow joint.

Living Suture Grafts in the Repair of Fractures and Dislocations.—Allen⁸¹ reported that he had employed strips of fascia lata for the suture of fractures of the patellae and olecranon in a series of patients who had been followed over a period of several years. The technic consisted in passing the strip through holes drilled in the fragments, crossing the ends on the anterior surface of the patella by passing one through the other and suturing the ends to the fascia or tendon above and below the fracture. The lateral tears in the aponeuroses were repaired with chromic gut. The advantages of the method were its strong mechanical fixation and the ability to stand the strain of motion begun at the end of one week. Splinting was not required. In the patients followed, there were no refractures and functional recovery was obtained at an earlier period than when the fragments were sutured by the usual methods.

Allen also successfully employed fascia lata for securing dislocations of the sternal end of the clavicle and for fixing the radial head in a patient with recurrent dislocation of this bone.

[ED. NOTE.—Allen developed his method of fascial repair of fractures of the patella and olecranon on the Fracture Service of the Massachusetts General Hospital, and the method has appeared to have so much advantage that it has been generally adopted by the other members of the staff.]

DISLOCATIONS

Fracture Dislocation of the Shoulder.—Gerard-Marchant⁸² made a study of fracture dislocations of the shoulder, including only those cases in which there existed a complete interruption in the continuity of the bone between the head and the upper part of the shaft. His conclusions were based on an analysis of 353 cases.

He found that the anteromedial type of dislocation was almost the rule, and that the fracture involved the surgical neck in 51 and the anatomic neck in 38.5 per cent of the cases. He was unable to note any difference in the type of the articular lesion accompanying the two varieties of fracture.

81. Allen, Arthur: *Living Suture Grafts in Repair of Fractures*, Arch. Surg. 16:1007 (May) 1928.

82. Gerard-Marchant, M. P.: *J. de chir.* 31:695 (May) 1928.

Reviewing the different methods of treatment and their results, he called attention to the fact that reduction might be accomplished in a certain number of patients by closed methods irrespective of whether the fracture involved the surgical or the anatomic necks. Complete functional recovery was obtained in about one half of the patients in whom reduction was accomplished by this means. Of the open methods of treatment, resection—that is, the excision of a larger or smaller entirely detached fragment—when performed soon after the injury, yielded on the whole imperfect results. The results of late resection were better. Replacement of the dislocated fragment by open operation performed soon after the injury gave results superior to those obtained by other methods. Late reductions gave varying results.

Actually, the methods of choice were, first, closed reduction and, second, open replacement. In fractures of the anatomic neck, these two methods appeared to be of about equal value; in fractures of the surgical neck, open replacement seemed to be the better method. Against closed reduction were the dangers of nerve injury or vascular rupture but, on the other hand, opening the articulation by surgical incision was not without danger. The open method ought not to have absolute priority over the closed method except in case of neurovascular lesions. In fractures of the surgical neck, one ought never to resort to resection. In fractures of the anatomic neck, resection might be indicated under certain conditions. In fractures involving the upper end of the humeral shaft, replacement could be the only aim. In the comminuted fractures in which the head escaped from the capsule in fragments, it was necessary to be sparing in the resection of the fragments.

Discussing the treatment for fracture dislocations of the shoulder, Taylor⁸³ described a method of treatment which he had successfully employed in several cases. Instead of manipulating or performing an open operation, he applied traction with the arm in abduction and the patient recumbent. He reported one case in which reduction was effected in four days. The fracture was reduced by increasing the degree of abduction of the arm to 120 degrees. Union was sufficiently solid in three weeks to allow immobilization in a plaster casing.

[ED. NOTE.—Of the various bony injuries, we know of none in which treatment is more difficult or prognosis more uncertain than fracture dislocations of the shoulder. When the fracture involves only the greater tuberosity the problem is relatively simple, and reduction can generally be accomplished by the closed method. Gérard-Marchant's conclusions as to the superiority of open replacement over resection are in accord with our own observations, although the operation is

83. Taylor, R. T.: Fracture Dislocations of Shoulder, *Arch. Surg.* **17**:475 (Sept.) 1928.

attended by much greater difficulty. Even then, complete functional recovery cannot be expected. We shall be interested to try the method described by Taylor. In obese patients, or when for any reason open operation is contraindicated, we think that there is something to be said for the old method of waiting for three to four weeks to allow the fracture to unite before attempting closed reduction.]

Dislocation of the Carpal Semilunar Bone.—Ettorre⁸⁴ preferred the term traumatic enucleation of the semilunar bone to dislocation, pointing out that the cases fell into two classes, one which he called a perilunar luxation in which the displacement was between the semilunar and the os magnum, the former maintaining its normal relation to the radius, and a second class in which the semilunar was dislocated anteriorly in relation to both the os magnum and the radius. He considered the second class as the true enucleation. He believed the type of luxation to be determined by the shape of the semilunar bone which had a variety of forms, and also by the strength of the ligaments as well as by the direction and force of the trauma. The author advised closed reduction in early cases in which the rotation of the bone was not complete. He warned of the possibility of injury to the median nerve in the manipulations.

AMPUTATIONS

Formation of the Gritti-Stokes Stump.—In thirty Gritti-Stokes amputations, Oehlecker⁸⁵ stated that he had fixed the patella to the femur by wedging it into an especially prepared mortise. He removed the cartilage from the under surface of the patella and shaped it into a square plug by means of a jig-saw. He then fitted this plug into a similarly shaped depression in the end of the femur. This method yielded a firm, painless end weight-bearing stump.

RESEARCH

Investigation of Adolescent Kyphosis.—Having been interested for several years in the subject of adolescent kyphosis and having published previous articles on the subject, Mau⁸⁶ undertook to reproduce the condition experimentally and reported the results. He sewed the end of the shortened tail of young rats beneath the skin, making a marked curve. The animals were killed and examined after different intervals. He found that definite changes developed in the epiphyseal cartilages; on the concave side, there was irregular proliferation and limitation of growth of the endochondral bone. The bony framework of the body underwent change and showed new formation of bony trabeculae, with

84. Ettorre, E.: *Chir. d. org. di movimento* 12:153 (March) 1928.

85. Oehlecker, F.: *Zentralbl. f. Chir.* 55:2250 (Sept. 8) 1928.

86. Mau, C.: *Ztschr. f. orthop. Chir.* 51:106, 1929.

the development of marginal proliferations such as are seen in arthritis; the body itself became wedge-shaped, with the apex toward the concave side. As a result of pressure atrophy, the margin of the epiphysis bordering on the concave side disappeared completely. Parts of the epiphyses showed necrotic changes. The author considered that the whole process was one of functional adaptation to a habitual curve and that the mechanism of these changes, which so closely resembled those seen in roentgenograms of patients with adolescent kyphosis, was one of circulatory interference.

Experimental Study of Muscle Atrophy.—Lippmann and Selig⁸⁷ produced muscle atrophy in rabbits by various means: immobilization of an extremity, section of a nerve, tenotomy and the production of an irritative arthritis. They found that atrophy due to immobilization alone was relatively small in degree and slow in onset as compared to that which followed arthritis, nerve section or tenotomy. They inferred that although arthrogenic atrophy had to be considered as an atrophy of disuse, it was not the result of immobilization but was caused by a reflex mechanism.

ARCHIVES OF SURGERY

VOLUME 19

AUGUST, 1929

NUMBER 2

OSTEITIS FIBROSA AND GIANT CELL TUMOR*

CHARLES F. GESCHICKTER, M.D.

AND

MURRAY M. COPELAND, M.D.

Research Fellows of the Bloodgood Cancer Research Fund, in the Surgical Pathological Laboratory, the Johns Hopkins Hospital and University

WITH FOREWORD BY

JOSEPH COLT BLOODGOOD, M.D.

BALTIMORE

FOREWORD

First, I would like to acknowledge our indebtedness to Mrs. Carl Joerissen, of Washington and Paris, and to those former patients and friends who contributed to the fund that made this research possible.

These two research fellows, Dr. Charles F. Geschickter and Dr. Murray M. Copeland, in the Surgical Pathological Laboratory of the Johns Hopkins University, began an independent study of multiple myeloma during the early spring of 1927, their senior year in the medical school, and continued their research in the laboratory and in the library. These studies were published in the *ARCHIVES OF SURGERY* in the April, 1928, issue, page 807.

During this time, they reviewed the entire collection of bone material in the laboratory, and thus prepared themselves for the more intensive study of all lesions of bone and all benign and malignant connective tissue tumors, beginning in July, 1928. Two papers are ready for publication: this one on the nature of osteitis fibrosa and giant cell tumor, and a second one, on the round cell sarcoma of bone, often of alveolar character, which is now grouped under the name of Ewing's sarcoma. These two papers, therefore, contrast the benign type of bone lesions with the malignant tumors. A third paper on osteogenic sarcoma is in process of preparation, and in this third contribution, which is the result of six months' research by the authors, an attempt will be made to present the differential diagnosis of the different types of benign and malignant tumors of bone and soft parts clinically, roentgenographically and microscopically—a presentation that has never been thoroughly made before.

It is only just to record that these papers present the personal views of these two students, and anything original that is presented should be

* Submitted for publication, Dec. 17, 1928.

* Publication aided by grant from the fund of the Hartley Corporation.

* Illustrations by Mr. Herman Schapiro.

credited to them. All that the laboratory did was to furnish them with the material for the study. It is my opinion that in these papers they have presented new, interesting and, I trust, correct pictures both of the nature of osteitis fibrosa and the giant cell tumor and of the nature of sarcoma, which not only will be valuable in the practical diagnosis and treatment of these lesions of bone in their earliest stage, but will form a basis for future progressive investigation.

I do not wish to anticipate in this introduction any of the statements made in the paper; I wish only to emphasize here and there some of the more important conclusions.

MALIGNANT GIANT CELL TUMOR

Although the authors are firmly convinced that osteitis fibrosa and the giant cell tumor are either identical or of natures closely allied, they have been unable, in the series of cases studied or in the literature, to find a proved case of malignancy arising in the benign bone lesion called osteitis fibrosa, which is situated in the shaft of bones of young persons. In spite of the fact that the age incidence of Ewing's sarcoma and of osteogenic sarcoma is the same as that of osteitis fibrosa, except that more cases of the malignant type are observed in persons more than 20 years of age, there is no evidence that these sarcomas develop in bone, the seat of osteitis fibrosa.

In the literature, there seem to be reported a few authentic and verified cases in which malignancy developed in a tumor involving the epiphysis of an adult which must be looked on as a benign giant cell tumor; that is, later in this benign giant cell tumor tissue, malignant sarcoma cells appeared, and gave rise to metastases in the lungs, in which also the giant cells were present. Together we studied all the cases in the literature and all the cases in our own series, and this research will be published later.

In the cases in which we have the material for study there occurred but one death from metastasis from a possible giant cell tumor of the epiphysis. In this case, the restudy of the sections of the original tumor classified it with the malignant variant of the giant cell tumor, of which we have had eight cases and only one of which metastasized. The other seven reacted as any giant cell tumor does. I think we can say here in anticipation of this publication that the danger of malignancy in a central tumor of the epiphysis which microscopically belongs to the giant cell group is so remote that one is justified in the conservative treatment by curetting or by x-ray radiation.

The histologic studies and illustrations presented in this paper by Geschickter and Copeland, I hope, will give surgical pathologists and pathologists a greater confidence in their ability to diagnose the giant cell tumor and to place it in the benign group. I have just visited a modern and thoroughly scientific surgical clinic in which the chief

surgeon is a well-trained surgical pathologist. Nevertheless, he presented to me a case in which, because of the microscopic sections, he feared malignancy in a giant cell tumor. The case offered a clearcut clinical and x-ray picture of a central tumor with an intact bone shell involving a condyle, or a little more, of the lower end of the femur. There had been an injury with a pathologic fracture, which had healed, and the curettement of the central tumor had followed some weeks after the healing of the fracture. The x-ray photograph therefore, showed a little formation of bone outside of the bone shell, and the microscopic section pictured in addition to the typical giant cell tumor, shown in the accompanying illustrations, young granulation tissue with cells of the morphologic type of the sarcoma cell, near islands of new bone formation, the result of the fracture. Unfortunately, the fear of malignancy in the giant cell tumor is still too prevalent, and only studies of this character will ultimately allay that fear. There should not be any difficulty in differentiating the variations in the typical giant cell tumor from the malignant variant (fig. A) and the fully developed sarcoma (fig. 21). It is important to emphasize here that the malignant tumors of the epiphysis are sarcoma developing in chondroma or myxoma. Ewing's tumor involves the epiphysis only secondarily from the shaft. The osteogenic sarcoma involving the epiphysis has an entirely different x-ray and microscopic picture. The metastatic tumor of the epiphysis is rare, but there should be no difficulty in differentiating giant cell tumor from metastatic carcinoma. The majority of bone aneurysms recorded in the literature were simply blood cysts with zones of giant cell tumor tissue in the epiphysis. In our series of cases there are but two bone aneurysms in which the tissue outside of the blood cavity, lining the bone shell, showed no evidence of the giant cell tumor. We have not observed a malignant aneurysm for more than twenty-five years,* and the tissue in the two cases is not sufficiently well preserved to allow an exact histologic diagnosis. Both these patients died of metastases. Their tumors may belong to the group we have designated as the malignant variant of the giant cell tumor, of which we have eight cases, in one of which death was due to metastasis.

This malignant variant of the giant cell tumor (fig. A), as stated before, can be easily recognized at the biopsy from the frozen section. I have no evidence that it should be treated any differently. The facts are these: One curetted in the upper end of the humerus eight years ago has not recurred; another has not recurred in three years; two have not

* Since this article was written, I have observed a third case of bone aneurysm in a child, aged 12. The roentgenograms showed a defect in the shaft similar to bone cyst, but the bone destruction suggested malignancy. At exploration there was a blood cyst surrounded by tumor tissue, microscopically osteogenic sarcoma. This roentgenogram of an osteogenic sarcoma resembles that of a bone cyst more than any other sarcoma that we have observed.

recurred on recent observations of one and two years since the curetting. In one case in which an amputation was done in 1905, the patient was living twenty-three years later. Two recurred. One was in the lower end of the fibula, which was resected in a few months, and the patient at the time of writing has been well for five years. The second was in the lower end of the femur; it recurred two years after curetting. The limb was amputated and the patient is living at the time of writing, six years afterward.

Fig. A.—The malignant variant of the giant cell tumor. Four large and several small giant cells are seen in the field. Among the small round cells of the stroma are larger cells with more cytoplasm and vesicular nuclei simulating sarcoma.

I am rather inclined to the view that if one finds a malignant variant of the giant cell tumor in the frozen section, it is wiser to resect and do a transplantation of bone, except in the lower end of the femur or the upper end of the tibia, where resection does not give as useful a limb as amputation and an artificial leg. Here one can try thorough curetting with chemical and thermal cauterization and irradiation to be followed by amputation if the tumor recurs.

To repeat, this small group of eight cases of the malignant variant of the giant cell tumor contains our only case of a supposed giant cell tumor which metastasized, and also shows a larger percentage of recurrences.

These eight cases of the malignant variant among 226 giant cell tumors were recognized by the authors when they first studied the microscopic sections without any knowledge of previous diagnosis or of clinical results.

RECURRENCE IN THE GIANT CELL TUMOR AFTER CURETTING

We have no record of a recurrence after resection. The only record of a recurrence in the stump after amputation was found in the literature, and in this instance the patient died of metastasis. The observation was made by Finch and Gleave of England and was reported in the *Journal of Pathology and Bacteriology* in the October, 1926, issue, page 329. We have thirty-two cases of recurrence after curetting. I presented the results of an investigation of the latter before the American Orthopedic Association in May, 1928, and the paper will be published in the *Journal of Bone and Joint Surgery*. From my studies, the chief factors in recurrence after curetting are: first, incomplete removal of the tumor, either because of hemorrhage or because of the inexperience of the operator; second, the failure to use chemical or thermal cauterization; third, attempting curettement when the bone shell is perforated or too much destroyed. There has been recurrence in the group with the latter condition in spite of thermal and chemical cauterization and in spite of preoperative and postoperative irradiation. I, personally, have had two cases which I have made the basis for my communication. The authors feel that in patients of more than 30 years of age, the danger of recurrence is greater than in younger persons, because the bone shell has lost its power to react and ossify.

RADIATION IN THE TREATMENT OF GIANT CELL TUMORS

Since my publication in the *Journal of Radiology* in March, 1920, I have repeated in every publication that it is wiser to put the doubtful bone lesions at rest and give x-ray treatment than to perform a biopsy, unless the operator or his pathologist has sufficient experience to make a differential diagnosis from the frozen section, and the patient is willing to have an amputation should the tumor prove malignant. Each year's experience confirms the truth of this. It is far safer to submit the x-ray photographs to others for help in diagnosis, employing radiation while waiting, than to perform a biopsy and send the section around for diagnosis.

In the past two years, the evidence has been increasing that persistent irradiation with x-rays or radium ultimately, in many instances, controls the giant cell growth. The tumor itself shrinks, and the x-ray

photograph shows increasing ossification. We are not yet prepared to make an exact comparison of the results after irradiation with those after curetting in properly selected cases. When we eliminate from our recurrent cases faulty curetting when the bone shell was intact and attempted curetting when the bone shell was destroyed, curetting has to its credit recoveries with perfect function in practically 100 per cent of the cases, and even if x-rays or radium could accomplish the same result in this group with intact bone shell, it would be more costly and take much more time. When the bone shell is destroyed, there is no question that irradiation should be tried first. Irradiation for recurrence after curetting is not so successful as irradiation without operation, nor has irradiation after recurrence following curetting prevented metastasis in the cases reported in the literature, notably the one reported by Ewing and Stone in the *ARCHIVES OF SURGERY* in 1923, page 289.

The question is, What is the danger of irradiation should the tumor be a chondrosarcoma or myxosarcoma? We have sufficient evidence to indicate that we may expect little or nothing of irradiation of the myxoma, or the chondroma, or the chondrosarcoma. The possibility of these tumors occurring in the epiphysis with x-ray pictures not unlike that of the giant cell tumor makes the problem difficult. In this malignant tumor of the epiphysis, the bone shell is usually partially destroyed. Therefore, from an x-ray standpoint, if the tumor is of the giant cell variety, the first treatment should be irradiation. I am not prepared to make any definite statement, but I am inclined to the view that, in doubtful cases, the nature of the lesion should be positively settled by a biopsy, provided the operator or his pathologist is competent to make a diagnosis. If not, irradiation should be the first method of treatment.

In conclusion, I want to call attention to the original view of the authors that osteitis fibrosa and the giant cell tumor are phases of bone repair; the first a healing reaction, the second an active vascularizing phase. In osteitis fibrosa, the tendency is to spontaneous reossification or healing. In the giant cell tumor this is not the case. Here the process leads to the formation of a mass of vascular tissue, in which giant cells predominate. The authors explain these different results with knowledge drawn from embryologic investigations of a new order.

Osteitis fibrosa and the giant cell tumor are specific lesions of bone and, in my opinion, are fundamental in all pathologic conditions of bone, just as chronic cystic mastitis is fundamental in all pathologic conditions of the breast, and, on the whole, is not unlike these benign lesions of bone in that it is a reaction of the parenchyma to some insult which, apparently, is not necessarily trauma, although trauma seems to be the starting point of osteitis fibrosa and the giant cell tumor. The authors also explain why osteitis fibrosa predominates in the shaft of bones in young persons and the giant cell tumor in the epiphysis of patients of a later decade.

INTRODUCTION

Since the time of Galen¹ a form of lesion related to osteitis fibrosa and giant cell tumor has been known to medical writers under the term of epulis, a tumor of the alveolar border. But the increased discussion concerning etiology, beginning with Nélaton's² contribution to giant cell tumor in 1860, and Virchow's³ description of a solitary bone cyst in 1876, has failed to furnish a unified conception of the underlying pathologic processes of this group of lesions, despite the constant progress made.

In this paper an attempt is made to show that a single group of pathologic processes concerned in the repair of injured bone is responsible for this group of clinical entities. The classifications, therefore, of osteitis fibrosa, giant cell tumor, epulis of the alveolar border and giant cell tumor in the tendon sheaths of the xanthoma type have been regrouped on the basis of a fundamental relationship established by the observations reported in this article. The material on which this report is based was made available by Dr. Joseph Colt Bloodgood in the Surgical Pathological Laboratory of the Johns Hopkins Hospital, and this group of over 400 cases comprises an accumulation of gross specimens, microscopic sections, x-ray pictures, clinical histories and a system of case follow-ups for which his personal efforts during the past thirty-five years are largely responsible. In addition to the references noted elsewhere, we wish to make special mention of the recent and larger series of cases contributed by Stewart,⁴ Simon,⁵ Bloodgood,⁶ Ewing,⁷ Kolodny,⁸ Coley,⁹ Barrie,¹⁰ Lewis,¹¹ Codman,¹² Christensen,¹³ and

MacGuire and McWhorter¹⁴ on giant cell tumor and by Silver,¹⁵ Knaggs,¹⁶ Elmslie,¹⁷ Bloodgood,¹⁸ Morton¹⁹ and Konjetzny²⁰ on osteitis fibrosa from which valuable corroborative data were obtained.

BONE CYSTS

Clinical Features.—Although the limits of osteitis fibrosa have been widely extended since the time of von Recklinghausen²¹ to include a multiplicity of entities, the solitary bone cyst, which is a form of osteitis fibrosa found usually in the shaft of the long bones of young adults, presents certain uniform characteristics which allow this group of lesions to be discussed separately from a pathologic standpoint.

Von Mickulicz²² was among the first to observe that the age of a patient with a typical bone cyst is usually less than 21. Bloodgood,¹⁸ writing on this subject in 1910, called attention to the fact that the patient was generally less than 18, and Silver,¹⁵ in his review of ninety-seven cases in 1912, found only eighteen cases in which the patients were past the age of 20. In a review of bone cysts, Elmslie,¹⁷ in 1914, found a similar age incidence. In 175 cases of bone cysts in this series, the average age of the patients is between 10 and 15, although in about 20 per cent the patients are more than 21. This age distribution is one of the outstanding clinical features of the disease.

More noteworthy than the age incidence is the location of these tumors, for in the large majority of cases of solitary bone cyst the lesions are confined to three favorite sites, the upper shaft of the femur, the humerus or the tibia. In Silver's¹⁵ table of ninety-seven cases, the tumor was found in the femur in thirty-one cases, in the humerus in twenty-five and in the tibia in fifteen. Elmslie¹⁷ was

impressed with the fact that the upper part of the femur and the upper part of the humerus were the prevalent locations for this type of lesion. The figures in our series are in accord with the observations of these authors. In 135 cases of solitary bone cysts, fifty-two were in the femur, forty-five in the humerus and thirty in the tibia. The fibula is next in frequency with eight lesions. In the cases in which the cyst was in the femur, thirty-two of fifty-two were present in the upper end, most of these being in the region of the greater trochanter. In the humerus, lesions in the upper end of the bone predominate, thirty-six of the forty-five cases in our series being in that locality, while in the tibia there is a similar predilection to involvement of the upper end. In all, about 75 per cent of these lesions showed a metaphyseal location in these three bones.

At the age and in the locality in which these tumors occur there is a relationship to an unossified epiphyseal line. The bone involved is therefore typically an area of new bone in a metaphyseal region. This fact would appear to relate the pathologic process involved to new bone formation, and in the microscopic study of these lesions, an attempt will be made to trace this relationship.

It is important to point out here that while the majority of bone cysts show this metaphyseal location, there is a fair percentage of them (16 per cent) which are found toward the region of the midshaft. This variation in site is explicable by the duration of the clinical symptoms. As will be seen from table 1, the average duration of symptoms is two and one-half years. In one fifth of the cases, the duration averaged ten years, and in several cases the patients had symptoms dating back from twenty to forty years. This long latent period preceding the diagnosis of the disease allows ample time for the affected area to progress gradually toward the region of the midshaft as the bone grows. In extreme cases in which from ten to forty years have elapsed, the reason for the occurrence of the bone cysts in patients more than 20 years of age is evident. Here the lesion takes the form of the so-called latent bone cyst discovered late in life as the consequence of some clinical incident leading to a roentgen examination, the previous presence of the tumor remaining unsuspected because of the absence of symptoms.

In accordance with this, a review of the histories shows that pain plays a mild rôle as a symptom of onset and that trauma with pathologic fracture or swelling is a more frequent cause in bringing the patient to the physician, pathologic fracture occurring in 45 per cent of the cases. In all cases we are impressed with the mildness of the clinical features, for only rarely is there extreme pain or marked bending deformity. The same facts are borne out by the clinical course which although protracted in many cases, is always benign, no patient ever dying from the direct cause of the disease.

X-Ray Features.—The typical x-ray picture of a bone cyst emphasizes many of the clinical features, the ununited epiphysis near the diseased area indicating the youthful age of the patient and the metaphyseal location of the lesions (fig. 1 *A*, *B* and *C*). A central area of bone destruction, which occurs most frequently in the upper part of the femur, humerus or tibia, casts little or no shadow in the roentgenogram and is crossed here and there by one or more trabeculations. About this area the cortex is thin and expanded to form a symmetrical and fusiform swelling. Often the bone is fractured at this site and along the margins of the fracture new bone formation casts a dense

Fig. 1 (nos. 35253, 34174 and 37796).—X-ray pictures of typical bone cysts in the localities most frequently affected: *A*, upper part of tibia; *B*, upper part of femur, and *C*, upper part of humerus. The lesions are near or at the metaphysis, and the ununited epiphysis in *A* and *C* indicate the youth of the patients. A pathologic fracture is shown in the upper part of the humerus.

shadow. These fractures tend to heal, and with healing the lesions frequently will ossify and disappear. When the diseased area persists for any length of time, however, the condition progresses toward the region of the midshaft.

The shell of bone about the affected portion is rarely perforated except by fracture. Often this portion of the bone is bowed or thickened. The new bone formation is then subperiosteal and cortical and produces no periosteal spicules, either parallel or radiating.

Gross Appearance.—The bone overlying the cyst varies in thickness according to the duration of the symptoms, the thicker shell encountered

in old cases indicating that a healing reaction is taking place (fig 2). A connective tissue lining is usually beneath the bone shell, and further toward the interior is the cavity which most frequently contains a serous fluid.

Bloodgood²⁸ has ably given a classification of the variations in the gross pathologic changes in these cavities or cysts. They may or may not have a connective tissue lining, and fluid or solid fibrous tissue may be found beneath. Calcium spicules like snow may be found on the inner side of the lining, or the remains of tissue resembling the grumous giant cell tumor may be disclosed.

Fig. 2 (no. 8324).—Gross specimen of a large bone cyst of ten and one-half years' duration in the lower end of the femur in a woman, aged 21. There is an unusually large amount of fibrous tissue and new bone formation in the cyst wall because of the age of the lesion.

In any event the contents of the cavity explored in the gross give little or no clue to an area of new cartilaginous bone such as the clinical features of age incidence and location would lead one to expect. In the shell of bone overlying the cavity, there is frequently a thickness and firmness extending into the fibrous lining which suggests the formation of new bone, but the location indicates that this is proceeding from the cortical region of the shaft rather than from a central metaphyseal location. Aside from this cortical reaction the gross specimens suggest a process of bone destruction rather than one of new bone formation.

Microscopic Analysis.—A microscopic analysis of the bone cyst, although adding much to our information concerning the pathologic

Fig. 3 (nos. 40124 and 24746).—Two typical areas of osteitis fibrosa. In figure *A* the intercellular substance is emphasized. In figure *B* there is condensation of fibrous tissue in the wall of the large cyst. A small cyst also is shown.

changes, fails to disclose in most instances a bone destructive process which would explain the cavity formation. Most of the tissue composing the cyst wall is fairly uniform and consists of spindle cells and fibroblasts among which there is much clear intercellular substance (fig. 3 *A*).

The tissue varies in relation to special areas. These special areas are of three main types: (1) cysts with or without old hemorrhage, (2) bone islands or bone trabeculae and (3) vessels in areas of fresh hemorrhage. Attention is first directed to the cyst wall. About the cyst wall there is a condensation of connective tissue to form a fibrous lining (fig. 3 *B*). Behind this lining layer embryonic fibroblasts are lay-

Fig. 4 (no. 19179).—*A* low and *B* high power of new bone formation in osteitis fibrosa. Osteoblasts derived from fibroblasts are laying down osteoid tissue. These spicules of new bone are characteristic of the process termed fibro-ostosis in this paper.

ing down intercellular substance, with the formation of osteoblasts and the direct proliferation of new bone. Occasionally, along the cyst wall or where two cysts walls meet with rupture in the wall, giant cell areas with round cells will be seen. Within the smaller cysts the remains of old hemorrhages are often found. In the larger cysts this is less likely to occur.

In regard to the substance around the bone spicules, the first or proximal row of cells is an actively proliferating layer of osteoblasts and numerous gradations between these cells and the fibroblasts (fig. 4 *A* and *B*). Beyond there is generally a loose fibrous tissue, almost myxomatous in appearance. Apparently, the process is from

spindle cell to fibroblast to osteoblast and then to bone formation, the bone at first being osteoid tissue previous to calcification.

Areas of fresh hemorrhage or new blood vessels present interesting features. Frequently an area with fresh blood will have a mixture of round and spindle cells in the neighborhood, or proximal to a new vessel will be seen a sprinkling of large giant cells of the epulis type (fig. 5). This relation of round cells and giant cells to spaces of red blood cells is most significant, and while some pathologists feel that giant cells are called on to absorb these hemorrhagic deposits (Konjetzny²⁰), it is important to emphasize that the giant cells are associated only with new vessels

Fig 5 (no. 28609).—Photomicrograph from a bone cyst showing a newly formed cyst containing red blood cells and surrounded by a sprinkling of giant cells.

and fresh hemorrhages rather than with the old blood seen within the cysts. For this reason it is more probable that the order of pathologic events so far as microscopic analysis can disclose them is: (1) the formation of giant cell areas followed by new blood vessels and hemorrhage; (2) the absorption of hemorrhage with cyst formation, and (3) the lining of the cyst by fibrous tissue which is gradually transformed into bone. In any event the three processes of hemorrhage, cyst formation and new bone construction which represent the special areas in osteitis fibrosa seem to be related and to have a definite influence on the character of the adjacent stroma.

Minute areas of calcification are often seen in the new bone laid down in osteitis fibrosa. Bone via the cartilaginous route as seen in osteogenic sarcoma, however, has not been observed, neither has true myxomatous tissue. Although much has been spoken about myxomatous degeneration in osteitis fibrosa, the interpretation placed on such areas here is that they are loose embryonic connective tissue.^{22a}

Nature of Osteitis Fibrosa.—The foregoing analysis of the histology of the cyst wall in osteitis fibrosa leads to the conclusion that the process involved is essentially one of fibrous proliferation and new bone formation and therefore a repair or healing process. We do not see in this tissue evidence of an inflammatory reaction, although repair in bone following a medullary abscess may show the same healing phase typical of osteitis fibrosa.

In keeping with this view of the nature of osteitis fibrosa tissue, is the experimental work of Macewen²³ in his studies on the growth of bone. He found as we do in sections taken from numerous areas in the bone, that regeneration takes place independently of the periosteum. The patients suffering from the lesions considered here are in the younger period of life when (as Macewen has pointed out) the proliferating power of the bone cell is at its height. The bone involved by the disease reacts vigorously, and we find bone formation taking place through the activity of osteoblasts in a medium of fibrous tissue, without the transitory stage of cartilaginous calcification. The photomicrographs illustrated in this article, and indeed most illustrations of osteitis fibrosa, show an exact duplicate of the process depicted in Macewen's²³ book on new bone produced experimentally, growing inside of glass tubes.

The conclusion that areas of osteitis fibrosa represent a healing reaction in bone, attacks seriously the claim of osteitis fibrosa to consideration as a pathologic entity. In accordance with this view are the records of the grading files made during this study. Here diagnosis in the osteitis fibrosa group showed the largest percentage of error. Abscess walls, bits of capsule from central sarcoma of bone, or secondary metastatic tumor, and periosteum overlying ossifying hematoma or exostosis were all inadvertently placed among the sections classed as typical osteitis fibrosa. From a standpoint of microscopic diagnosis, it was a veritable dumping ground. The reasons for this are to be found in the non-specific nature of the tissue reaction, erroneously termed osteitis fibrosa. It is not an inflammation in fibrous tissue or in bone but a process of

22a. This loose embryonic connective tissue as pointed out by Leriche and Policard (Physiology of Bone, St. Louis, C. V. Mosby, 1928) is a pre-osseous edema pervading the connective tissue, and is always the first step in bone formation in this tissue.

23. Macewen, W.: The Growth of Bone, Glasgow, James Macelhose and Sons, 1912, figs. 27 and 28.

repair constituting a natural defensive reaction of cancellous bone, cortical bone and periosteum against pathologic invasion, whether the invading lesion is an abscess, a sarcoma or a giant cell tumor (figs. 6 *A* and *B* and 7).

In most cases of osteitis fibrosa this healing reaction is found around an evacuated area of bone destruction. The solitary bone cyst under

Fig. 6 (no. 36614).—Bone cyst formed about a foreign body. *A* is an x-ray picture and *B* is a photomicrograph from the same case. The patient was struck by a piece of flying steel eighteen months previously, the steel entering the hand. The superficial wound healed. Fourteen months later, swelling and pain occurred at the site of injury. The x-ray picture shows the cyst about the foreign body. The photomicrograph shows fibro-ostosis (new bone and fibrous tissue) surrounding an area of granulation tissue.

discussion shows such an area of bone destruction in the form of an enclosed cavity, and about it is the typical healing reaction which we believe is best termed fibro-ostosis (indicating new bone formed directly from fibroblasts). The reparative nature of this reaction of fibro-ostosis is evidenced clinically by the benign course of the disease and the tendency of the lesions to undergo spontaneous healing. Clinically and pathologically too, it would seem that the bone destructive process soon becomes arrested or often progresses without noteworthy symp-

Fig. 7 (no. 15745 [Bone Tumors: Group 9]).—Section taken from the margin of a Ewing's sarcoma of bone. The undestroyed bone is reacting to form a protective wall about the tumor, laying down new bone surrounded by osteoblasts. These new bone spicules with the surrounding fibrous tissue resemble osteitis fibrosa. A nest of round sarcoma cells is seen in the upper portion of the picture.

toms, for when we recognize the condition clinically and make the diagnosis or explore, the bone destructive phase is practically always complete and nothing is encountered but the healing phase. This fibroid process of repair sometimes extends over a period as long as forty-five years, and then a latent bone cyst is recognized. The persistence of the cyst beneath this healing reaction is due to nature's difficulty in collapsing

a cavity with rigid walls, and when fracture or a crushing procedure at operation aids in collapsing this cavity, the lesion heals.

HISTOLOGIC VARIANTS OF THE BONE CYST

The question arises as to what is the original bone destructive process in the bone cyst. In the average case the lesion is of two and one-half years' duration when first observed, and at the end of such a period the condition responsible for the area of bone destruction has disappeared. When bone cysts are grouped according to the duration of symptoms, however, and when the group in which the symptoms average six months are examined, we are able to discover by microscopic examination the nature of the process which forms this cavity in the bone. This group of early cases shows in the x-ray picture a metaphyseal location and a polycystic structure. Twenty-nine in the series of one hundred and seventy-five cases of bone cysts were in this group. Microscopically, they were all classed as giant cell variants of osteitis fibrosa. By this is meant that areas of large multinucleated giant cells embedded in a stroma of round cells, a tissue typical of a giant cell tumor, were always found in early cases of bone cysts examined pathologically. This confirms our microscopic analysis of the typical bone cyst, for as pointed out in the foregoing, there were histologic grounds for assuming that the giant cell areas preceded those of osteitis fibrosa.

In other words, we are inclined to the belief that the bone destructive phase of osteitis fibrosa is characterized by typical tissue of a giant cell tumor. More broadly stated, the average solitary bone cyst in the long bones is a healed or healing giant cell tumor. Not only do twenty-nine early cases of 175 cases of osteitis fibrosa show marked giant cell areas, but sixty cases of giant cell tumor of a series of 226 cases show a healing change toward osteitis fibrosa, most marked at the margins of the tumor but also infiltrating toward the center.

This does not mean that all bone cysts are healed giant cell tumors, nor is it true that giant cell tumors will all progress toward a healed state of osteitis fibrosa. In bone cysts 2 per cent of the cases can be shown to have a bone destructive phase due to a foreign body (fig. 6) or an abscess, and in about 20 per cent of the cases rather loosely classed as osteitis fibrosa some primary disease such as osteomalacia, Paget's osteitis deformans, fragilitas ossium, or osteo-arthritis is responsible for this cyst formation. The majority of solitary bone cysts (78 per cent), however, show their relationship to a preceding giant cell tumor phase (1) by the persistence of giant cell areas most frequent in the younger cysts with a shorter duration of symptoms, and (2) by the fact that these lesions are on the metaphyseal side of the epiphyseal line, bordering on the epiphysis in which giant cell tumors occur.

The polycystic group of osteitis fibrosa also emphasizes the relation of the bone cyst to giant cell tumor tissue, for in these lesions the small young cysts can be seen arising in giant cell areas and fusing together to form the larger cavities.

Detailed consideration of the lesions grouped under the variants of osteitis fibrosa in the metaphyseal ends of the long bones (table 2) and under the classification of polycystic osteitis fibrosa (table 3) brings out more forcibly the basis on which these conclusions rest.

Giant Cell Variants of the Bone Cyst in the Metaphyseal Ends of the Long Bones.—Clinically, these lesions are of shorter duration than

Fig. 8 (no. 17121).—Giant cell variant of osteitis fibrosa near an epiphysis. The x-ray picture, *A*, shows a lesion in the region of the greater trochanter which is inclined to be polycystic. There has been a pathologic fracture. The photomicrograph, *B*, from the same case shows numerous giant cells embedded in the stroma of osteitis fibrosa.

the typical bone cyst. The average duration in the group of cases tabulated in table 2 (with two exceptions) is six months. None of these lesions is found in the region of the midshaft, their location being invariably on the shaft side of the epiphyseal line, close to the area in which typical giant cell tumors occur. A favorite site for these hybrid bone cysts is the region of the greater trochanter in the femur, in which the condition occurred in six of the sixteen cases listed in the series (fig. 8, *A* and *B*). Here it will be recalled there is a separate epiphyseal line in youthful patients, which would seem to indicate that the trans-

formation of cartilage to bone taking place in this locality has some bearing on the pathologic process involved.

In the x-ray picture and in the gross this group of lesions is inclined to be more subcortical than central in location, and the structure is most frequently multilocular. When this polycystic character was particularly marked under the microscope, the lesions were grouped separately under the classification of polycystic osteitis fibrosa.

On microscopic examination the present group of cases of osteitis fibrosa contain giant cells which are smaller, have fewer nuclei and are more sparsely distributed than one would expect for a typical giant cell tumor located in an epiphysis. In the stroma, too, there are more fibro-

Fig. 9 (no. 34990).—A giant cell variant of osteitis fibrosa in the metaphysis (x-ray picture and section from the same case). *A*, the lateral and anterior x-ray views showing the typical fusiform lesion of the bone cyst extending to the epiphyseal line. The duration of symptoms was four months. *B* is a photomicrograph of one of the numerous giant cell areas found amid the osteitis fibrosa tissue in this lesion, demonstrating the tendency of the bone cyst to assume a giant cell structure when it borders on the epiphyseal line in an early stage of the disease.

blasts, more intercellular substance and more bone islands. However, small areas of larger giant cells surrounded by a narrow zone of round cells are met with here and there in the sections (fig. 9 *A* and *B*). Hemorrhages are a rather prominent feature of these lesions, and here the giant cells are apt to dispose themselves about the hemorrhage and about the cyst wall. The bone islands are the same as those found in osteitis fibrosa and are surrounded by osteoblasts.

The relation of this histologic picture to the relatively brief duration of the symptoms is again brought out by the recent cases referred to the surgical pathologic laboratory for diagnosis. Since patients have been consulting the physician more promptly during the last decade than ever before, sections from exploratory operations on bone cysts have shown, almost without exception, the inclusion of giant cell areas in the osteitis fibrosa tissue.

Polycystic Osteitis Fibrosa.—Two views may be taken concerning these lesions which are generally referred to by the name of polycystic osteitis fibrosa. One view is that they are an early stage of osteitis fibrosa, assuming a structure characterized by an aggregation of small cysts because a fusion of these small cavities at a later date represents the mode of origin of the large solitary cysts. The second view would be that such lesions are a more progressive form of bone cysts, and that their continued growth by the apparent budding of small cavities represents a transition between the solitary bone cyst (which is an arrested lesion) and the multiple form of osteitis fibrosa which is undoubtedly progressive. Some truth resides in both these views.

A survey of the cases in our series and those from the literature shows that in a large portion of cases the multiple bone cysts take on the structure of polycystic lesions. Hence, this peculiar multilocular structure is associated with the invasive nature of generalized osteitis fibrosa. On the other hand, when this polycystic structure is observed in a single bone (fig. 10 *A* and *B*), these lesions occur near the epiphyseal line in the metaphysis indicating an early stage in the transition from giant cell tumor to an arrested cyst. The most important feature, however, of this polycystic structure is that under the microscope these small cysts are surrounded by tissue rich in large multinucleated giant cells (fig. 31). This microscopic structure shows that elements of the bone destructive lesion of giant cell tumor persist and that the arrested stage characterized by fibro-ostosis and a scarcity of giant cells has not yet been reached. This lack of complete healing is explained on the one hand by the short duration of the symptoms and the proximity of the lesions to the epiphyseal line and on the other hand by the presence of multiple bone involvement indicating a generalized disease of the skeleton (table 3).

Knaggs,¹⁶ in his excellent review of osteitis fibrosa, stated that he was convinced that there is an earlier bone destroying stage in the pathologic process of bone cysts which is responsible for these lesions. He remarked, however, that he had never seen such an early stage nor a description of it in the literature. This early stage, we believe, is seen in all giant cell variants of osteitis fibrosa, and nowhere is it better exemplified than in this particular group of polycystic lesions known to

Fig. 10 (no. 28609) — *A*, polycystic osteitis fibrosa invading the epiphysis of the fibula; *B*, photomicrograph showing beginning of fusion in several small cavities. Note the association of red blood cells with the cysts.

the literature for over twenty-five years. The failure of the pathologic changes in this lesion to show its earliest stages has not been in the tumor but rather on the part of the pathologists in failing to recognize the significance of the histologic picture. This conclusion is justified by the appearance not only microscopically but also clinically. The duration of symptoms in this group of lesions when they occur singly near an epiphysis averages about five months compared to two and a half years for the typical bone cysts if one or two unusual cases are omitted. In the x-ray picture too, these lesions are found most often to be situated in a subcortical location rather than centrally, and this asymmetrical position is characteristic of both early giant cell tumors and early bone cysts as will be demonstrated later. From a histologic standpoint, the picture of multiple small cysts frequently filled by hemorrhage and sur-

rounded by giant cells exhibited by this group of tumors has all the characteristics essential to the interpretation of it as a transitional form between the giant cell tumor and the bone cyst.

GIANT CELL TUMOR

Since an examination of the giant cell variant and polycystic forms of osteitis fibrosa leads to the conclusion that giant cell tumor tissue is the earliest phase in the pathologic process of bone cyst, an analysis of the typical giant cell tumor is in order. From its relationship to the bone cyst it is to be inferred that this typical giant cell tumor is an entity with a shorter duration of symptoms, with a tendency to involve bone newly formed from cartilage (in an epiphysis), and that it is primarily a bone destructive lesion with a slighter degree of healing reaction of the same "fibro-ostosis" character. Such inferences are confirmed by an analysis of more than 200 giant cell tumors reported in the following tables.

Clinical Features.—Clinically, the giant cell tumor is a progressive, bone destroying lesion occurring at any age in the epiphysis, where osteo-

* All the lesions listed were in an epiphysis.

genesis proceeds until late in life. The maximum number of cases (40 per cent) occur in the third decade between the ages of 21 and 31 years, or about a decade later than the average bone cyst. This is in keeping with the difference in locality of the areas affected. Whereas the bone cyst favors the metaphyseal ends of the upper part of the humerus, femur and tibia, the giant cell tumor selects most frequently the epiphysis of the lower part of the femur and radius and the upper part of the tibia (table 4). Ossification in the epiphysis persists later in life than in the metaphyseal regions and accounts for the age difference between these two tumors.

Although the giant cell tumor is typically benign, case follow-ups show thirty-two recurrences in a series of 226 cases indicating that the tumor is usually progressive and must be eradicated by proper treatment. Omitting five cases which gave the unusual history of a duration of from six to nine years, the average time when the patient first came under observation was fourteen months after the onset, as compared with the average for the typical bone cyst of thirty months. The usual sequence of symptoms was trauma, pain, tumor and fracture—trauma being present in 42 per cent of the cases and pathologic fracture in 14 per cent (table 5).

X-Ray Features.—The x-ray pictures of this tumor emphasize its bone destructive character. The lesion generally assumes an asymmetrical position in an epiphysis, a comparison of early and late lesions showing that the area of bone destruction begins in a subcortical location at one side of the epiphysis and works its way toward a more central location at the expense of cancellous bone (figs. 11, 12 and 13). The expanded bony shell of the tumor is extremely thin and, in slightly less than 100 cases examined roentgenologically in this series, was found perforated in 60 per cent of the lesions. Trabeculae traverse the diameters of the tumor when the shell of bone is intact, but as the tumor becomes larger, the trabeculae and then the bone shell disappear, the tumor extending into the soft parts. Such extension is aided by pathologic fracture when it occurs (fig. 14 *A* and *B*). In even relatively advanced lesions there is no periosteal reaction, and central areas of new bone formation are wanting.

Gross Appearance.—The gross appearance of the typical giant cell tumor shows the same bone destruction featured in the x-ray pictures, but demonstrates more clearly the limited but definite healing reaction about the margin of the tumor. The gross appearance of the tumor mass itself is usually hemorrhagic in nature. As Bloodgood stated, it is usually like an old bruise, every grade from red to black, although occasionally it is a uniform gray, putty color. At the operation, when touched, it bleeds, oozing like a sponge. When crushed, it is friable like

Fig. 11 (no. 25778).—*A*, anterior, and *B*, lateral x-ray views of a giant cell tumor in the lower end of the femur. Note the asymmetrical location of the lesion and the extreme thinness of the bone shell. The trabeculae have almost disappeared.

Fig. 12 (no. 32277).—*A*, anterior, and *B*, lateral x-ray view of a giant cell tumor in the upper end of the tibia. The bone shell is still intact; trabeculae are present.

Fig. 13 (no. 37708).—Giant cell tumor in the lower end of the right radius. The bone shell is perforated on the lateral side, and the trabeculae there are disappearing.

Fig. 14 (no. 37360).—*A*, x-ray picture, and *B*, gross specimen of a pathologic fracture through a giant cell tumor in the lower end of the femur. Fracture has aided the tumor in the invasion of the soft parts

cheese. Fibrous areas may be palpated in the gross, extending inwardly like partitions from the capsule. These are the trabeculae seen in the x-ray picture, and under the microscope they are fibrous septums resembling osteitis fibrosa.

The encapsulation of the tumor mass is sometimes effected by a connective tissue envelope, resembling in many respects the leathery fibrous capsule of the bone cyst. In the gross, the reaction of fibro-ostosis is most pronounced in the cortical bone on the shaft side of the epiphysis. Here the cortical bone thickens and extends downward from the shaft toward the epiphysis preceded by fibrous tissue. The cancellous bone extending across the medullary cavity on the shaft side also lays down a fibrous barrier to the tumor which may result in a capsule visible in the gross, but more often discernible only under the microscope when sections are made from this region.

In the epiphysis itself, in which the tumor is situated, the lateral margins present contrasting reactions. Because of its asymmetrical position the tumor borders on cortical bone on its outer side in early lesions, while inwardly, cancellous bone is infiltrated. The border of cortical bone resists longer and more effectively the advances of the tumor. Its reaction consists in the laying down of new bone and fibrous tissue (fig. 15 *A* and *B*). The natural structure of cortical bone, however, is extremely thin in this region of the epiphysis as will be seen from figure 16, and ultimate perforation through its wall is by no means rare. The superiority of its defense over cancellous bone is demonstrated, nevertheless, by the fact that the tumor expands centrally to the opposite side of the epiphysis in most instances before the cortical shell gives way. The joint cartilage, to which point the lesion generally extends because of its epiphyseal location, resists successfully the invasion of the joint cavity. Its defense is by means of calcification of its already compact substance, the calcified tissue being transformed into bone (figs. 17 and 18).

Thus it will be seen that everywhere about the tumor normal structures are endeavoring to stem the invasion. When this reactive tissue is examined microscopically, it shows a histologic structure typical of the fibro-ostosis seen in the wall of the bone cyst. Indeed the microscopic structure of the giant cell tumor differs from that of the bone cyst, not in kind but only in degree. Here there is more giant cell tumor tissue and less fibro-ostosis, while in the bone cyst there is a preponderant fibrous proliferation and new bone construction with little or no remnant of giant cell tumor tissue. Microscopically, these giant cell areas represent the fundamental pathologic change underlying these lesions, and a careful study of them discloses the nature of giant cell tumor.

Fig 15 (no 32924) —*A*, gross specimen, and *B*, microscopic section of a giant cell tumor in the lower end of the fibula. The photomicrograph shows a reaction of new bone and fibrous tissue in the tumor capsule. The new bone has taken on a deep stain.

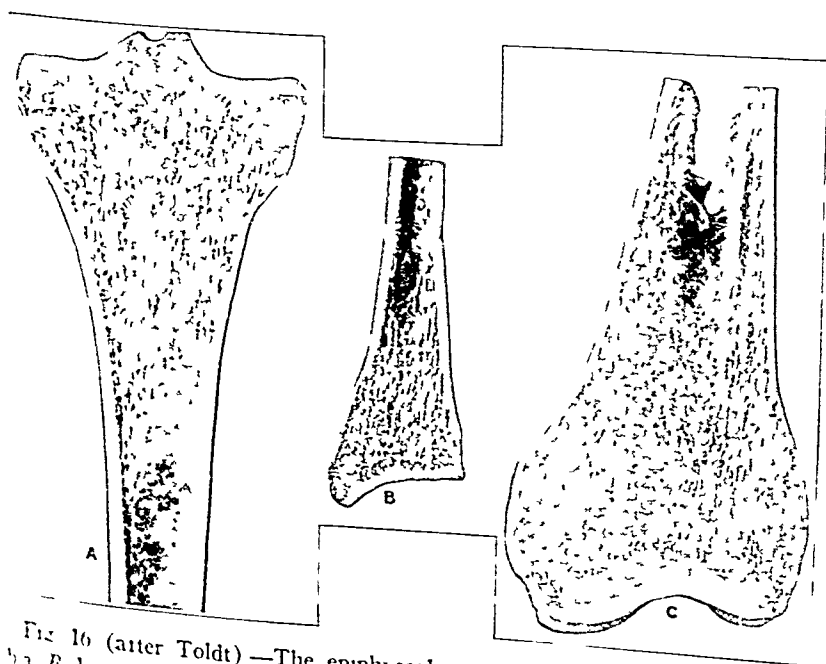

Fig 16 (after Toldt) —The epiphyseal regions of the *A*, upper part of the radius, *B*, lower part of radius and *C*, lower part of femur. Attention is directed to the normal cancellous structure of the epiphysis and the thinning of the cortex and compact bone and periosteum in these regions.

Fig. 17 (no. 27001).—Giant cell tumor in the upper end of the tibia. The tumor extends to the joint cartilage. No fibrous reaction is discernible here in the gross in the cut section. Fibrous tissue may be seen overlying the outer surface of the tumor on the uncut surface.

Fig. 18 (no. 10975).—Photomicrograph showing the reaction of joint cartilage. The cartilage has become calcified and is laying down compact bone to resist the invasion of the giant cell tumor.

Microscopic Analysis.—The tumor mass proper, of the typical giant cell tumor, which is responsible for the bone destruction observed in this lesion and also in the bone cyst, is composed essentially of large multi-nucleated giant cells embedded in a mass of smaller round cells (fig. 19 *A* and *B*). The giant cells average over 30 cells per field under the low power, with the number of nuclei in each cell varying from 15 to 200. The cells range in size from 10 to 100 microns and may or may not have distinct borders to the cytoplasm.

The number of giant cells present varies from field to field, being more numerous about areas of hemorrhage, about spicules of old bone or about the walls of minute cysts. The typical giant cell tumor, how-

Fig. 19 (no. 37360).—*A*, low, and *B*, high power photomicrographs of the typical giant cell tumor. There are over thirty cells to the low power field and the usual number of nuclei is over fifteen per cell. In the high power it will be seen that round cells predominate the stroma.

ever, maintains with remarkable regularity, in most areas, a crowding of large multinucleated elements. Giant cells with few nuclei relatively small and sparsely distributed are not typical of the benign giant cell tumor and are more characteristic of the variants of osteitis fibrosa and osteogenic sarcoma (figs. 20 and 21).

An outstanding peculiarity of the typical giant cell tumor is the cellular stroma in which the giant cells are embedded. Two kinds of cells can always be found in this stroma, the round and spindle cell, but in the typical giant cell tumor group, the round cells outnumber the spindle cells in every instance. This small round cell has a relatively large nucleus and a small amount of cytoplasm. There is a definite

nuclear wall and a nucleolus. The nucleus is generally from 3 to 7 microns in size with a fairly large amount of chromatin evenly distributed, and the borders of the cytoplasm are usually indistinct.

There is, apparently, a definite relationship between the round cell of the stroma and the giant cell. In the first place, when the giant cell predominates the tumor by its numbers, the round cell prevails in the

Fig. 20 (no. 32013).—The giant cell variant of osteitis fibrosa. Note the small size and scarcity of the giant cells and the large number of spindle cells and fibroblasts in the stroma. Microscopically, the tumor is benign.

stroma. Moreover, the nuclei of the giant cell always have the same general form and staining characteristics as the nuclei of the round cells. The only important variation is the tendency for the giant cells to have a more acidophilic cytoplasm with occasionally a greater concentration of chromatin in the nuclei and other signs of early degeneration. This

could be accounted for by a seniority in the age of the giant cell, the inference being that the giant cells are formed by agglutination of the round cells in the stroma.

Conspicuous in the histologic structure of giant cell tumor is hemorrhage. Red blood cells in a well preserved state infiltrate the tumor more often unenclosed by endothelial walls than otherwise. The typical

Fig. 21 (no. 39274 [B.T. 9]).—Osteogenic sarcoma with giant cells. Two giant cells are present in the field, each having less than fifteen nuclei. The most important diagnostic feature of the section is the presence of the large vesicular nuclei, some of which are undergoing mitotic division.

giant cell tumor is thus both hemorrhagic and vascular, newly formed vessels being by no means rare. Areas of organizing hemorrhage are frequent, and bordering on these is loose edematous tissue intermingled with areas of osteitis fibrosa.

Spicules of bone are frequently found near the margin of the tumor or at its capsule. Some of these spicules are undoubtedly surviving portions of old bone undergoing destruction (fig. 22), to be recognized by the giant cells applied to their surface, the condensation of calcium salts at the margins, the frayed and worn edges, and the small size of the bone cells included in the matrix of the spicules. Other spicules with osteoblasts applied to their surface are new bone resembling those fre-

Fig. 22 (no. 14229).—Spicules of old bone being attacked by giant cells. The margin of the spicules shows condensation of lime salts, worn and broken edges, and giant cell osteoclasts applied to the surface. The bone cells within the spicules are small, and fine linear markings are still present in the matrix.

quently seen in osteitis fibrosa, and represent a healing reaction rather than bone of tumor origin.

The spindle cells conspicuous about the new bone spicules are found elsewhere in the tumor among the round cells of the stroma. They are oval and slender in form with a nucleus rather well defined and a cytoplasm elongated but sparse, without definite outlines. Fine fibrils surrounding these spindle cells indicate their fibroblastic tendencies and

identify them with the same type of cells seen in osteitis fibrosa. When these spindle cells predominate the stroma in giant cell tumor, they indicate a healing process and mark the section as a variant (the spindle cell or osteitis fibrosa variant) of the giant cell tumor. This important group of hybrid tumors demonstrates a transitional phase between giant cell tumor and osteitis fibrosa.

TRANSITIONAL LESIONS BETWEEN THE GIANT CELL TUMOR AND THE BONE CYST

The so-called spindle cell variant of the giant cell tumor and the group of multiple giant cell tumors and multiple bone cysts demonstrate by their transitional structure the unity of the pathologic process underlying both the bone cysts and the giant cell tumor. These two transitional forms will be considered separately.

The Spindle Cell Variant of the Giant Cell Tumor.—It has been shown that the encapsulation of the giant cell tumor is accomplished by a healing reaction at its margin resembling in morphology, osteitis fibrosa. This healing reaction of fibro-ostosis predominates in sections taken from the margins of giant cell tumors, and for this reason twelve of the sixty cases graded as spindle cell variants of the giant cell tumor were found on further study to be taken from such areas in otherwise typical giant cell tumors. In this group of twelve cases a single section under the microscope would often show a giant cell area, a border of spindle cells, a further outlying zone of osteitis fibrosa and a final region of proliferating cortical bone, demonstrating clearly the nature of the healing reaction and the attempt by nature to lay down a defensive wall (fig. 23).

A special investigation was undertaken to verify this interpretation of the spindle cell tissue as a healing reaction. Blocks for sectioning were taken from various portions of the tumor margin in thirty gross specimens and examined. Sections taken from the region of cortical bone on the shaft side of the giant cell tumors always showed a marked protective reaction, histologically resembling in every respect fully developed osteitis fibrosa. The same was true of sections taken from a well formed connective tissue capsule, particularly where the periosteum joined in the formation of the capsule. When other sections were made from the region of cancellous bone either in the epiphysis or in the medullary cavity on the shaft side of the tumor, the defensive reaction was less pronounced but evident, and the infiltrating areas of giant cells in fibrous tissue gave the histologic picture typical of what has been called the spindle cell variant (fig. 24). Even when sections were taken at the point where tumor perforated and infiltrated into the soft parts, there was the same fibrous reaction, although under the microscope

Fig. 23 (no. 17706).—Section taken from the periosteal margin of a giant cell tumor. New bone formation preceded by a layer of fibrous tissue is attempting to wall off the tumor.

Fig. 24 (no. 11855).—A giant cell tumor showing spindle cell variation near the tumor margin. Spindle cells are infiltrating about the large giant cells.

avenues had been opened up in this tissue through which giant cells were streaming (fig. 25). Even on the cartilage side of the tumor margin toward the joint, the reaction was evident, calcified cartilage with transition to compact bone abutting on tumor area.

In thirty-seven cases showing this spindle cell variation under the microscope (tables 6 and 7), the fibroid change was fairly uniform throughout the tumor. This group of cases was of unusual interest because histologically it was practically impossible to make the distinction between giant cell tumor and bone cyst. Clinically, they were all

Fig. 25 (no. 26091).—Giant cells perforating the new bone of the tumor capsule. The channel in the lower portion of the picture is the line of perforation. The giant cells are deeply stained, and no definite structure is visible. The poor staining is due to the age of the specimen from which this particular area was selected for sectioning.

located in bones other than the long pipe bones, eight were in the vertebrae and twenty-nine were in the small bones of the hands and feet or in the flat bones. The interpretation placed on these lesions was that they represented giant cell tumors in which the healing reaction was unusually prominent. The clinical follow-up on this group of cases confirmed this. None of these patients died of tumor if we may except one which proved inoperable when a laminectomy was attempted on a

tumor near the sacral region. With this exception, the other patients are well without signs of recurrence whereas in the typical giant cell tumor, there is about 20 per cent of recurrence following similar treatment.

This group of lesions raises the question as to why the giant cell tumor of the epiphysis fails to heal and is a progressive lesion, while a similar tumor in the small or flat bones progresses partially toward healing and the bone cyst arising in the metaphysis of the long bones presents a predominately healing reaction. The explanation lies in the differences in the anatomic structure of the bones involved. The epiphysis is to be associated with the giant cell tumor, the metaphysis with the bone cyst and the small or flat bones with the spindle cell variant of giant cell tumor. The epiphysis in which the typical giant cell tumor occurs lacks the defensive mechanism represented by the thick cortex of the metaphysis and diaphysis of the long bones and the overlying periosteum which as Macewen²³ and Poland²⁴ have pointed out, is equipped in the shaft and the metaphysis with a rich and vascular osteogenic layer which is lacking in the epiphysis after the age of 3 years. Hence, the giant cell tumor progresses in the epiphysis, whereas the bone destructive lesion in the metaphysis is reacted to effectively by the cortical bone in that region, and as the bone grows, the cyst or tumor area in the metaphysis is pushed toward the region of the midshaft within the protective confines of the thick cortical bone as a walled-off cavity (fig 16). On the other hand, in the small bones, spacial limitations bring the developing tumor almost immediately into relation with cortical bone on all sides of the growth. An active defensive reaction against a giant cell tumor occurring in these bones is, therefore, set up early, and microscopically exhibits itself as a fibrous proliferation resulting in the so-called spindle cell variant. This early stimulation of compact bone on all sides of the lesion to produce fibro-ostosis makes it hard to find a region in a giant cell tumor of the small bones that is not invaded by young fibroblasts (figs. 26 *A* and *B* and 27 *A* and *B*). This tendency toward repair, however, although invoked early is not so marked as in the shaft of the long bones in which the cortex is thicker and more active.

The fact that lesions with characteristics of the giant cell tumor in small bones are often diagnosed as bone cysts demonstrates their healing tendencies. We feel, however, that the maintenance of two categories for diagnosis of these lesions in the small bones is unjustified. For years cases showing this type of tumor in the small bones have been shifted back and forth, classified first with bone cysts and then with giant cell tumor or vice versa, two independent classifications being maintained for a single pathologic entity. It is clear that these lesions are giant cell tumors, showing a fair degree of healing reaction when

24. Poland, J.: Traumatic Separation of the Epiphyses, London, 1898.

they have the appearance of a spindle cell variant and a further degree of healing reaction when they appear as osteitis fibrosa with giant cell areas. Certainly they are not the mythical entity of a cyst in the small bones secondarily invaded by giant cells.

Dean Lewis¹¹ in his paper on "Giant Cell Tumor of the Vertebrae" approaches this point of view. In this contribution Lewis reviews seven-

Fig 26 (no. 17436).—Giant cell tumor in the os calcis. The x-ray picture, *A*, shows mottling and bone destruction. The shell of bone is intact. The microscopic structure, *B*, shows a spindle cell variant of the giant cell tumor.

teen cases including one of his own, pointing out that recovery after partial removal or exploration only, has been noted in thirteen of the seventeen cases, ossification occurring relatively frequently. In his series, the condition in two cases was located in the transverse processes of the lumbar vertebrae, two in the lamina of dorsal vertebrae and the

majority of the remainder (as far as can be determined from the case reports) in the lateral portions of the vertebral body next the lamina. As will be seen from figure 28 the site of these vertebral tumors in the region of compact bone and the early defensive reaction of fibro-ostosis produced, accounts for the healing emphasized by Lewis. Fortunately, sections from one of Lewis' cases are in the laboratory, and like the six of our own (fig. 29) the sections show spindle cell variation. Perforation and extension into neighboring bones occur more frequently in giant cell tumors of the spindle cell group (twelve of seventeen in Lewis' series), but this is only because they so frequently occur in small or flat bones in which the cortex is always thin and other bones are in close

Fig. 27 (nos. 26953 and 17536).—The x-ray picture, *A*, shows a giant cell tumor of the terminal phalanx of the midfinger. There is involvement of both shaft and epiphysis in this small bone, and the tumor has perforated at the distal end. The photomicrograph, *B*, shows a giant cell tumor in the phalanx of a toe. Portions of trabeculae of cancellous bone are undergoing absorption, while the proliferation of fibroblasts in other areas shows a healing reaction.

approximation (fig. 30). Extension is not due to increased virulence of the tumor, as some pathologists claim who consider the spindle cell variant of the giant cell tumor a malignant form of this lesion (Ewing⁷).

From these studies the locality of the bone affected is seen to be an essential and determining factor in the pathologic process of giant cell tumor and the bone cyst. The epiphysis with its less active periosteum and thinner cortex allows the bone destructive giant cell tumor to

Fig. 28 (after Triepel-Breslau: Anat. Hefte 25:209, 1904).—Cross-section of a lumbar vertebra showing the relation of cancellous to compact bone. As is explained in the text, the most frequent site of giant cell tumors is in the region of the laminae in the body, in the transverse process or in the lamina itself. This brings the tumor into contact with compact bone at an early stage.

Fig. 29 (no. 38530).—Giant cell tumor of a vertebra. The giant cells are embedded in a stroma in which there are many spindle cells.

progress, while the thicker and more resistant cortex of the metaphysis, with its vascular subperiosteal layer promotes healing and makes for an arrested lesion, the bone cyst.

There is another factor of great importance, however, namely age. Bone growth and a bone cell with great proliferating potentialities are characteristic of youth. This power to heal a bone destructive lesion in the early years of life accounts for the fact that the arrested lesion, the bone cyst, is three times more frequent before the age of 20 than the

Fig 30 (no 24682) —Gross specimen showing the involvement of the third and fourth metacarpals by giant cell tumor. There is extension of the bone destructive process to several bones

unhealed giant cell tumor (fig. 31). In fact, although several cases of bone cysts are recorded in this series in the epiphysis in patients under 5 years of age, giant cell lesions in any locality were not observed in patients under that age. The reason for this is that the vascular subperiosteal layer of the epiphysis does not begin to atrophy until after the age of about 3, and hence giant cell lesions arising in the epiphyses will be transformed into bone cysts at these earlier ages by the active periosteum

Figure 31 emphasizes how the age period influences the physiologic factors underlying the differences between giant cell tumor and bone cyst. In this chart it will be seen that giant cell tumors do not occur until after the age of 5 when the periosteum of the epiphysis has lost much of its reparative powers. The healed bone cyst is the predominant lesion during the active growth period when the regenerative power of bone is at its height. To state it briefly, within certain age limits, as the healing powers of bone decline the frequency of the bone cyst decreases, while the frequency of the giant cell tumor increases.

Multiple Giant Cell Tumor and Multiple Osteitis Fibrosa.—A perusal of the contributions to this subject shows that a clinical and

Fig. 31.—The age incidence of giant cell tumor compared with that of bone cysts. Within certain age limits (from 10 to 25) as the healing powers of bone decline, the frequency of bone cysts decreases while that of giant cell tumors increases.

pathologic overlap has long been recognized in this group of multiple tumors between bone cyst and giant cell tumors.^{24a} Morton,¹⁹ in reviewing the literature of multiple bone cysts, divides the lesions into group 1 without giant cell sarcoma and group 2 with giant cell sarcoma. In a similar manner, Alexander and Crawford²⁵ divide multiple giant cell

24a. Both Henderson (Minn. Med. **11**:542, 1928) and Meyerding (J. A. M. A. **83**:1323 (Oct. 25) 1924) recognized a relationship between these two tumors in their reports on solitary giant cell tumors.

25. Alexander, E. G., and Crawford, W. H.: Multiple Giant Cell Tumors, Ann. Surg. **86**:362 (Sept.) 1927.

Fig 32 (no. 37250).—Multiple giant cell tumors occurring in the tibia, radius, antrum and both maxillari (gross and microscopic specimens from the same case). *A* and *B* are gross specimens showing the polycystic structure of the tumor; *C* is a photomicrograph showing the numerous large multinucleated giant cells occurring in a cyst wall.

tumors into two groups, those without and those with associated fibrocystic osteitis.

A review of our series of cases (table 8) emphasizes that in females past the age of puberty the condition predominates and that the males affected are usually under 12 and in these patients the condition is frequently associated with other juvenile diseases such as rickets, congenital syphilis, osteogenesis imperfecta and fragilitas ossium. Thus at the beginning of this discussion, it is important to realize that in cases of either multiple giant cell tumors or multiple bone cysts, there is frequently an associated disease, such as is not found in the single bone cysts and local giant cell tumors. Silver¹⁵ implied this when he excluded from consideration in his article cysts occurring in seven different groups of associated diseases. This fact of a complicating disease, however, is not sufficiently emphasized in the reports on this group of tumors, and it must be borne in mind in the following discussion.

Multiple Giant Cell Tumor.—Many important features of the multiple giant cell tumor are illustrated in the following case (path. no. 37250, figs. 32 *A*, *B* and *C* and 33). The patient observed in 1922, was a white woman, aged 21, and the condition was of nine years' duration. The patient was well in 1928. The lesions were in the right tibia, the left radius and both humeri, all occurring just on the diaphyseal side of the epiphyseal line. In addition to this there was a tumor in the left antrum. The specimens illustrated were from the right tibia. In the gross the tumor was polycystic, and under the microscope even smaller cystic areas were present in large numbers. Giant cells predominated in the tissue about the cyst wall, and among these giant cells were numerous round cells. Elsewhere the stroma was composed of spindle cells and fibroblasts and further out there were islands of new bone and typical osteitis fibrosa. There was much hemorrhage in the tissue, and some small cysts were occupied by blood.

There were too many giant cells in the sections for the tumors to be classed as simple cysts. Similarly, we have never observed a case of typical bone cyst in the upper jaw. Yet, the tumors in the long bones are all on the shaft side of the epiphysis, and the patient was only 15 years of age when these lesions first appeared. These two facts and the polycystic nature of the tumor favor osteitis fibrosa, and the sections show numerous areas to this tissue. How is a combination of giant cell tumor and bone cyst to be explained in the same case?

Usually, the single bone cyst is an arrested lesion as we have shown, an arrested giant cell tumor. When it is multiple, and particularly when it is polycystic, we have reason to believe that the general rule has been broken and that the lesion has become progressive. In the above case

TABLE 8.—Multiple Giant Cell Tumor and Bone Cyst

Path. No.	Race, Sex, Age	Location	Symptoms	X-Ray	Treatment	Microscopic	Associated Disease	Results
37229	W. M. 12	Upper humerus, upper lower radius, upper fibula, upper femur	Trauma	Cystic expansion	No operation	No note	Osteogenesis imperfect	Well less than 5 years

the age of onset and the location of the tumors in the metaphysis of the long bones would seem to indicate that had this tumor become arrested, it would have been a typical bone cyst. Instead it had become progressive, showed multiple bone involvement, polycystic structure and a predominance of giant cells, the expected explanation for this failure to be arrested being that there was an associated disease in the skeleton that prevented the usual protective overgrowth of fibro-ostosis from taking place.^{25a} When we review all the multiple cases in the literature, and those in our collection, we are impressed with two facts, that the patients are either females at the age during which osteomalacia occurs or males and young girls at the age in which juvenile bone diseases are common. The associated skeletal diseases vary, but some complicating factor is usually present (fig. 34, *A* and *B*) such as osteogenesis imperfecta, rickets, congenital syphilis, fragilitas ossium and osteomalacia.

From the facts already mentioned, the conclusions follow that most multiple giant cell tumors would, without a complicating factor, develop clinically into a bone cyst and that their failure to become so arrested and the persistence of giant cell areas in them indicate a progressive lesion. The giant cells present indicate the more primitive and original structures of these lesions, and ordinarily they disappear from the healing solitary bone cysts by the time that the lesion comes under observation. These multiple giant cell tumors, therefore, throw considerable light on the earlier stages of osteitis fibrosa.

Multiple Bone Cysts.—A review of multiple bone cysts in the literature and in our own series emphasizes the fact that the lesions described under this head represent a conglomeration of pathologic entities.

25a Although in this case we had at our disposal only the history, x-rays and microscopic material, and although we were unable to verify the conclusion by metabolic studies, the fundamental conception advanced here has been recently confirmed by evidence placed at our disposal through the courtesy of Dr. R. M. Wilder of the Medical Division of the Mayo Clinic. The case, that of a white woman, aged 32, studied by him over a period of four years (to be reported in *Endocrinology*) duplicates in its essential clinical features the one already outlined, and in addition shows abnormal calcium and phosphorus values in the blood serum which ultimately proved dependent on a hyperparathyroidism associated with a benign adenomatous tumor of the parathyroid gland. Giant cell tumors occurred in the lower part of the femur, the upper jaw and at the site of the right lower bicuspid (epulis). The serum calcium was elevated to 11.4 mg. per hundred cubic centimeters, and the phosphorus lowered to 1.4 mg. per hundred cubic centimeters. As a result of this removal of lime salts from the bones, the pelvis showed rarefaction and distortion similar to osteomalacia and the skull and spine areas of absorption. Improvement followed removal of the parathyroid tumor, a diet high in vitamins and ultraviolet light therapy. The serum calcium had returned to 8.3 mg. per hundred cubic centimeters and the phosphorus to 1.8 mg. per hundred cubic centimeters when the patient was last examined in April, 1929.

Fig 33 (no 37250) —Low magnification of the cyst shown partially in figure 32 C. The numerous black dots in the tissue are seen to be giant cells under higher magnification. The broken septum dangling from the roof of the cyst shows that the fusion of two minute cysts has occurred.

Fig 34 (nos 25247 and 28074) —Two cases showing associated skeletal disease with multiple bone cysts and multiple giant cell areas. The bending of the bones and the pathologic fractures are associated with fragilitas ossium (A) and osteoporosis imperfecta (B).

When selected on a microscopic basis, these lesions show under the microscope a predominance of osteitis fibrosa, fewer, but some giant cells, and less of the polycystic structure. Clinically, this group is to be distinguished from multiple giant cell tumors by the higher age limits and the longer duration of the symptoms. This is what would be expected if multiple bone cysts represented a later stage in the same pathologic process as multiple giant cell tumors. When outspoken cases of Paget's osteitis deformans, osteomalacia, osteoarthritis and similar diseases are excluded, all the evidence is found to support this view. When the cysts were large and the tissue sparse in giant cells, we found the average age of the patients to be higher and the duration of the symptoms to be longer (table 8). Ultimate healing without surgical intervention occurs in multiple bone cysts, the process responsible for the multiplicity of the lesion apparently subsiding, although the cysts themselves may remain many years as latent lesions. In such cases it will not be possible to find an associated disease when these lesions come under observation at a late date.

In passing it is well to note here certain observations made in this group of multiple bone tumors. In the majority of the twenty cases in this series studied in this laboratory the urine was examined for Bence Jones bodies. In all cases the results of the examination were negative, an interesting diagnostic point in view of the frequency of Bence Jones bodies in the urine of patients with multiple myeloma (65 per cent), and the association of these bodies with other multiple bone tumors (Geschickter and Copeland ²⁶).

THE NATURE OF THE GIANT CELL

It has been pointed out that the giant cell tumor under the microscope shows a typical structure characterized by many large giant cells embedded in a round cell stroma. The spindle cell variant of this histologic picture and indeed, the microscopic structure of osteitis fibrosa and its variants were shown to be due to a healing reaction or fibro-ostosis in most instances superimposed on the original giant cell picture. In this way and also by pointing out transitional lesions, it was shown that these various forms of disease of the bone in all probability originate from a single underlying pathologic process characterized histologically by the proliferation of giant cells. A fundamental importance, therefore, attaches to the elucidation of the nature of the giant cell and the causes for its proliferation.

In contrast to the bone formative tissue of fibro-ostosis, giant cell areas in the skeleton are associated with bone destruction. This is well

26. Geschickter, C. F., and Copeland, M. M.: Multiple Myeloma, *Arch. Surg.* 16:807 (April) 1928.

illustrated by figure 35 which shows a bone spicule lying at the margin of a giant cell tumor occurring in the lower epiphysis of the femur. At one end, the spicule is enlarged and club-shaped and in contact with it are numerous osteoblasts applied to its surface. Surrounding this enlarged end, beyond the osteoblasts, are numerous spindle cells and fibroblasts. At this end there is little doubt that new bone formation is taking place. At the other end the spicule is narrower, and the margins are frayed and worm eaten in appearance. Near at hand are giant cells

Fig. 35 (no. 3623).—A bone spicule from the margin of a giant cell tumor in the lower end of the femur. At the large end of the spicule, osteoblasts embedded in fibrous tissue are laying down new bone. At the small tumor margin of the spicule, the frayed and worn edges indicate bone destruction. Both the bone destructive nature of giant cell tumor and the healing reaction of fibro-ostosis are illustrated by this section.

embedded in a round cell stroma. The histologic picture at this end of the spicule is that of typical giant cell tumor, and it is plainly evident that bone destruction is occurring here.

Varieties.—The question arises whether the giant cells in the tumor are responsible for this bone destruction and if the tumor process repre-

sents a proliferation of osteoclasts as pointed out by Stewart of Leeds.⁴ Much work has been expended in an endeavor to determine whether the giant cell erodes bone. The question has not been conclusively settled, although a well defined distinction has been drawn between giant cells of the hemopoietic series, giant cells in malignant tumors with rapid mitoses, and foreign body giant cells. The so-called osteoclast or giant cell of the epulis type found in giant cell tumor is undoubtedly related to the foreign body type. It represents a formation of cells characteristic of a phagocytic process, and as Lewis²⁷ has shown, these larger elements are formed by the fusion of smaller cells, with occasionally a further multiplication of nuclei by mitotic division. Giant cells of this phagocytic type are found when agar-agar is introduced into muscle, about foreign bodies introduced into wounds, about gummas and tubercles, epithelial pearls in squamous cell carcinoma and about necrotic fibrous tissue in other tumors. The presence of these cells in such a miscellaneous group of lesions is probably to be explained on a basis of a chemotaxis to a collagen-like substance present in all of these conditions. It is important to recall in this connection that Leriche and Policard^{22a} have recently shown that a collagenous matrix is fundamental to the formation of all bony substances.

But though related to the foreign body type in formation and phagocytic nature, the giant cell of giant cell tumor with its typical retinue of round cells is by no means to be confused with the foreign body giant cell embedded in granulation tissue. No particular histologic training is necessary to distinguish between these two types of tissue, and the current tendency to regard giant cell tissue everywhere as granulation tissue and to interpret all tumors of this form on such a basis is unjustifiable despite the contentions of Mallory,²⁸ Konjetzny²⁰ and many others.

Histologically the giant cell in granulation tissue is a smaller cell, with fewer nuclei, peripherally rather than centrally placed. The surrounding round cells are leukocytes of various types and are relatively small. The giant cells although clumped rarely average as many as 10 or 15 cells to a low powered field. In typical giant cell tumor tissue the giant cells are larger, have more nuclei (from 15 to 200) centrally placed and average over 30 to the low powered field. The accompanying round cells are not of the infectious leukocytic type but are larger, more uniform in size and structure, and their nuclei correspond in morphology to the nuclei of the giant cells.

27. Lewis, W. H.: Mononuclear Blood Cells, The Harvey Lectures, 1925-1926, series 21, p. 83.

28. Mallory, F. B.: Giant Cell Sarcoma, J. M. Research **74**:463, 1911.

Fundamentally there is a difference, and while recognizing the giant cell of the epulis type as related to the foreign body series, we view it as a specialized form and propose to demonstrate the osteoclastic nature of all giant cell tumors and their inherent relation to bone even when occurring in the soft parts.

Such a view of the osteoclastic giant cells interprets them as phagocytic elements which exhibit the property of giant cell formation when bone or calcified cartilage is being resorbed. The question of whether the giant cells directly or indirectly, mechanically or chemically are accomplishing the bone destruction is irrelevant to this discussion. Suffice it to say, that they are an early manifestation rather than an end-product of bone destruction as claimed by Arey,²⁹ and they may be taken as an index that the process is active, since when this type of tissue proliferates the process increases. Embryologic studies emphasize this point.

The Relation of the Histogenesis of Intracartilaginous Ossification to Giant Cell Tumor.—Although works on embryology since 1890 (Quain³⁰) give the histogenesis of the long bones in some detail, the importance of this process for giant cell tumor made a reconsideration of the whole process essential. For this purpose we were fortunate in having the privilege of studying a most valuable collection of human embryos in the Carnegie Institute of embryology placed at our disposal through the courtesy of Professor Streeter, director of the institute.

In the long bones, the process of osteogenesis is similar in both the shaft and the epiphysis, the two being formed by intracartilaginous ossification. There are usually three centers of ossification, one for the diaphysis and one for each epiphysis. The center of ossification of the shaft develops first, new bone extending in two directions toward each metaphysis. The two epiphyseal centers develop much later (fig. 36). Hence, the areas in which new bone formation persists in the child and the young adult are in the metaphysis of the bones on the shaft side of the epiphyseal line and in the epiphysis. As we have seen, these persisting centers of ossification are the sites of the lesions of bone cysts and giant cell tumor. The histologic processes going on in these regions or centers explain how these growths arise.

The new bone is preformed in cartilage and later replaced by permanent bone. This process may be said to take place by transformations occurring in three stages: (1) the calcification of cartilage to form primary areolae; (2) the invasion and resorption of the areolae and

²⁹ Arey, L. B.: Origin and Fate of Osteoclasts, *Am. J. Anat.* **26**:315, 1919-1920

³⁰ Schafer, E. A., and Thane, G. D.: Quain's Elements of Anatomy, ed. 10, 1911, vol. 1, part 2, pp. 268-284.

their walls; (3) the laying down of permanent perichondral bone. Both longitudinal and transverse sections are necessary to a clear conception of these three stages, and both are illustrated here (figs. 36 to 41). In the longitudinal sections the ends of the bone are still primitive cartilage. Toward the center of the shaft, the cartilage cells line up in rows, enlarge and secrete an increased hyalin matrix which becomes calcified to form a honey-combed arrangement. The cartilage cells within these calcified

Fig. 36 (no. 40936).—The femur of a monkey fetus at term. The photograph illustrates the persistence of cartilage in the epiphysis and the formation of new bone in the metaphysis. The marrow cavity is not yet fully formed.

compartments next shrivel and atrophy, their nutrition being cut off by the calcified walls which form the primary areolae. All this occurs in the regions that are the future medullary cavity. In the subperichondral region (what is to be subperiosteal) along the margins of the shaft, osteoid tissue is being laid down by the perichondrium. In the next stage, this perichondral osteoid tissue is perforated by blood vessels that proceed inwardly to the primary areolae (fig. 40 *A* and *B*).

This stage in which the calcified areolae are invaded by blood vessels and resorbed is the most significant phase for the understanding of giant cell tumor and is best seen in cross-sections taken from the long bones of young human embryos. It is just this phase that is most poorly described in the textbooks, and the cross-sections illustrated here are usually omitted. In the transverse sections it will be seen that the primary areolae are invaded and resorbed by buds of tissue proceeding from the outlying mesenchyme surrounding the perichondral bone. The manner in which these buds perforate the perichondral bone, invade the calcified areolae and absorb them is most important. Mesenchymal cells

Fig. 37 (no. 40936).—Photomicrograph of the epiphyseal line of the femur shown in figure 36. Cartilage has calcified to form the primary areolae. Giant cells or osteoclasts are eating their way into the calcified cartilage followed by small vessels, preliminary to the formation of permanent bone. Cells of the newly formed marrow cavity are seen at the bottom of the picture.

concentrate, their nuclei darken and the cells agglutinate to form giant cells or osteoclasts. These giant cells are first to perforate the perichondral bone (fig. 41) and the first to force entrance into the compartments of the calcified areolae (figs. 37 and 38). In their wake come newly formed capillaries, osteoblasts and other mesenchymal elements. When the stage of resorption of calcified cartilage is at its height, and the medullary cavity is being formed, a cross-section of a young bone in an embryo of from 90 to 100 mm., taken from this region, will show a

veritable giant cell tumor. The cavity of the bone will be filled with giant cells, round cells, small blood vessels, hemorrhage and osteoblasts. Later the osteoblasts persist near the margin of the medullary cavity to aid in the formation of cancellous and then compact bone, while the marrow cavity itself becomes filled with young bone marrow elements.

These embryologic studies emphasize the association of the giant cells with the perforation of new perichondral bone and the resorption of calcified cartilage. The specimens show clearly that the giant cell

Fig. 38 (no. 40936) —Higher magnification of the same area shown in figure 37. Three primary areolae formed by calcified cartilage with a portion of two others are shown in the photomicrograph. One areola is still intact, and in it two degenerating nuclei of cartilage cells are seen. In the other areolae giant cells are seen forcing their entrance through calcified cartilage. Note that the nuclei of the giant cells are entirely different in morphology from those of the degenerated cartilage cells, and that they outnumber the cells in the calcified area. This disproves the statement of Arey that giant cells are rarely seen when calcified cartilage is undergoing resorption and that the giant cells are formed as a by-product of degenerated dissolving bone by the agglutination of the nuclei of old bone cells.

proceeds inwardly from outside of the shaft of the bone and that these multinucleated elements may arise in the primitive periosteal tissue. It is not necessary to presume that they arise from the marrow reticulum as many histologists believe (Maximow³¹) nor that they are derived from the endothelium of capillaries. The only distinct evidence is in favor of the view that they are formed from primitive mesenchyme and that such mesenchyme exists periosteally.

Giant cell formation, therefore, marks the beginning of bone perforation in the embryo, and in the wake of these cells new blood vessels and osteoblasts follow. Over and over again in both giant cell tumor and osteitis fibrosa, particularly of the polycystic variety, we have observed giant cells on the outward borders of new blood vessels and vascular spaces (figs. 5, 45 and 57) showing that the giant cells in these lesions retain the same histologic function as the osteoclasts seen in human and other mammalian embryos.^{31a}

Other points of interest in the embryologic processes of bone are the formation of perichondral osteoid tissue directly from the mesenchymal osteoblasts without the medium of cartilage which parallels exactly the bone formation described in this paper as fibro-ostosis, and the resemblance of calcified cartilage in the embryo to analogous tissue seen in osteogenic sarcoma.

Turning now to the consideration of giant cell tumors, the location of these lesions (and also the healing form of bone cysts) at the sites and at the ages when intracartilaginous bone is being formed relates them to this process. More specifically and convincingly the bone destructive character of these lesions and the prevalence of giant cells or osteoclasts in them relates them to the process of resorption of temporary bone characterized by the proliferation of osteoclasts or giant cells which has been described in the foregoing review of histogenesis in the long bones. From this we conclude that the giant cell tumor and the related lesion of bone cyst are the result of an abnormal hyperplasia of osteoclasts preceded by a normal stage in which osteoclastic proliferation is taking place as a phase in the histogenesis of intracartilaginous bone. From this point of view, the term progressive osteoclastasia is suggested for the process underlying the giant cell tumor and the term

31. Maximow, A.: Untersuchungen über Blut und Bindegewebe, Arch. f. mikr. Anat. 76:1, 1910.

31a. That this same histologic function of the osteoclasts as forerunners of the vascularization and resorption of temporary calcified structures holds for repair processes and even for foreign bodies is shown by the experiments of Pollock and others on the viability of transplanted bone (Arch. Surg. 18:607 [Feb.] 1929). Here in experimental bone transplants it was found that giant cells attacked the transplanted bone preliminary to its vascularization and the formation of new bone.

regressive osteoclastasia for bone cysts. These terms show their relationships one to the other and also to the normal process of osteoclastic proliferation that goes on in the histogenesis of the long bones.

GIANT CELL TUMORS OF THE SKULL

The validity of the hypothesis which relates giant cell tumor to the resorption of temporary bone or calcified cartilage is to be proved by the elucidation and the prediction of the facts in regard to these tumors wherever they are found. So far as giant cell tumors and bone cysts in the long bones are concerned, this conception holds, for by age incidence,

Fig. 39 (no. 40978).—High power field of an epiphysis of a child 11 months old showing calcified cartilage attacked by giant cells. This shows a similar process which is more clearly illustrated in figures 37 and 38.

location and histologic structure these lesions are related to osteogenesis via cartilage. However, tumors of the giant cell variety occurring in the skull, along the alveolar border in the form of the giant cell epulis, and in tendon sheaths and soft parts offer greater difficulties in the establishment of this relationship to the resorption of temporary bone. To predict such a relationship for giant cell tissue in this diversity of lesions is to bring the conception of giant cell tumor thus far advanced to a crucial test. In order to carry out this test these various types of lesions will now be examined in detail.

The Chondrocranium in Relation to Giant Cell Tumors of the Skull.

—If the intimate association of the pathologic changes in giant cell lesions to the resorptive process in cartilaginous bone is a fact, then the bones of the skull and face should furnish valuable evidence to support it. For it is known that certain bones of the cranium—particularly the frontal, parietal and tabular portion of the occipital—which compose

Fig. 40 (no. 40934).—Cross-sections of the humerus of a human embryo of 90 mm. The upper section, *A*, shows the perforation of the perichondral osteoid tissue by mesenchymal elements at numerous points proceeding inwardly from the primitive periosteum. The calcified cartilage is about to undergo resorption by these invading mesenchymal elements. *B* is a section near the region of the mid-shaft of the same bone, showing a more advanced stage in the resorption of calcified cartilage by mesenchymal elements and the formation of the marrow cavity. Note how the subperichondral osteoid tissue has been broken through at different points. (Sections furnished through the courtesy of Dr. Streeter of the Carnegie Institute of Embryology.)

the calvarium are formed from membrane rather than cartilage, as are most of the bones of the face. These bones should be immune to direct involvement by either osteitis fibrosa or giant cell tumor. It is true that they are provided with periosteum and that this tissue retains osteoclastic as well as osteoblastic potentialities, but in such instances, the lesion should be periosteal instead of central and present other peculiarities. A review, therefore, of the exact histology and location of giant cell tumors of the head becomes of special significance.

Fig. 41 (no. 40934).—Higher magnification of the section shown in figure 40 A. The photomicrograph illustrates the first step in the resorption of calcified cartilage. A giant cell proceeding from the primitive periosteum is perforating the perichondral osteoid tissue and attacking the primary areola. In its wake is shown a small blood vessel and other mesenchymal elements arising from the primitive periosteum. The picture disproves the assumption by numerous embryologists that the giant cells of an osteoclastic nature are formed from the reticulum in the marrow cavity, for here we see that the giant cell is entering the future marrow cavity from the periosteum outside of the bone.

Excluding the epulis of the alveolar border the records of the surgical pathologic laboratory of the Johns Hopkins Hospital extending over a period of thirty-five years show only twenty-two cases of giant cell

tumor occurring in the head. Bone cysts did not occur in this locality. Two of the giant cell tumors were found in the temporal fossa, six are recorded for the upper jaw and fourteen in the lower jaw. In the purely membranous portion of the calvarium (the frontal and parietal bones), not a single instance of these lesions is recorded (tables 10 and 11). The three sites of the lesions, the temporal fossa, the upper jaw and the mandible, it is true, are in regions of membranous bone. The squamous portion of the temporal bone, the superior maxillae and a large portion of the mandible are formed from membrane. But there are also cartilaginous centers of ossification in the neighborhood of the temporal fossa, the maxilla and the mandible. It becomes necessary.

therefore, to delineate carefully the areas of bone derived from cartilage in the skull and to examine the twenty-two lesions recorded to determine whether their locations coincide with such cartilaginous areas.

Table 9 from Jordan and Kindred³² summarizes the essential points in the histogenesis of the chondrocranium. The same information is duplicated diagrammatically in figure 42. Here the portions of the skull derived from cartilage are represented by areas in black, and in figure 43 the twenty-two lesions occurring in the skull have been plotted according to location. It will be seen at a glance that the giant cell tumors in the lower jaw which is the most frequent site for these tumors of the skull coincide in locality with centers of intracartilaginous ossifica-

tion for the mandible. The two lesions in the temporal fossa are associated with the wing of the sphenoid (which is derived from cartilage) projecting into this locality. These facts are further substantiated by

* Multiple tumor in other bones

the data in table 10. In this table it is seen that in the mandible most of the giant cell tumors occur at the symphysis where Meckel's cartilage participates in the formation of this bone. The others are located at the ramus where there is a separate center for cartilaginous ossification. Table 11 also correlates the origin of the lesions in the temporal fossa

with cartilaginous centers in the sphenoid bone projecting into this region. The only discrepancy is apparently in regard to the six lesions of the upper jaw. In table 11, however, it is seen that all of these tumors found their way either into the antrum or into the orbital fossa. The ethmoid bone which is entirely derived from cartilage is in relation to both of these cavities as is shown in figure 44 *A* and *B*.

The fact that neither bone cysts nor giant cell tumors can be found in the portions of the skull which are entirely of membranous origin and the fact that they always occur at least in proximity to areas of cartilaginous ossification is more than suggestive if not convincing. Such evidence is worthy of scrutiny in more detail.

Giant Cell Tumors of the Temporal Fossa.—The history of two such cases are on file in the surgical pathologic laboratory. Only the

Fig. 44 (from Lothrop: *Ann. Surg.* **38**:233, 1903).—*A*, horizontal section above the level of the ostium maxillare. Within the figure, *A* indicates the antrum with arrows indicating the position of the ostium maxillare and lying in the infundibulum; *U*, uncinate process; the cavity just external to the letter is the infundibulum; *a, a*, anterior ethmoid cells; *p*, posterior ethmoid cells; *s*, septum nasi; *O*, orbital fossa; *m. t.*, middle turbinates. The posterior half of each turbinate is horizontal; the anterior half is vertical, and each instance the turbinate contains a cell (*c*). The dark space external to these turbinates is the middle meatus, and the long, dark area internal to the turbinates divided by the septum is the general cavity of the nasal fossa. The anatomic specimen shows the ethmoid bone which is formed from cartilage outlined in black and demonstrates the relation of this bone to the antrum and orbit. *B* (after Frazer: *The Anatomy of the Human Skeleton*, p. 245) is a diagram illustrating the position of the labyrinth of the ethmoid in relation to the orbit and antrum.

first is reviewed here because the records of it are complete in every detail. The patient was a white woman, aged 52, with pain near the right ear of three years' duration, and dizziness for six months. Exami-

nation showed deafness in the right ear, ataxia with deviation to the right, swelling over the right temporal region and a negative cerebrospinal fluid. At the operation the tumor was partially removed by excision. There was extension about the base of the pons which was deemed inoperable. Four years after operation the patient had a fully developed hemiplegia due to the continued growth of the tumor left behind. Under the microscope sections of the tumor showed a typical giant cell lesion

Fig. 45 (no. 37914).—A giant cell tumor arising from the body of the sphenoid and presenting in the temporal fossa. Attention is directed to the relation of the giant cells to the newly formed blood cavity.

(fig. 45). Careful inquiry into the operative notes shows that the origin of the lesion was from the posterior body of the sphenoid extending into the great wing around the carotid groove. This definitely relates the tumor to a center of cartilaginous ossification.

Giant Cell Tumors of the Upper Jaw.—All six of these tumors of the upper jaw presented into the antrum and one involved the floor of the orbit as well. Two of the six were multiple lesions occurring also

in other bones as will be seen from table 11. Tissue taken from the antrum was examined microscopically in every case except in the two multiple lesions, where tissue was taken from other bones (in one case the lower jaw, in the other the tibia), the histologic nature of the antrum tumors being inferred. In every case, the tissue was graded as a spindle cell variant of giant cell tumor, microscopically. In all of them careful search, where the records were sufficiently detailed, related these lesions to the ethmoid bone which would account for their origin from a cartilaginous center and the tendency of these tumors to present in the antrum or the floor of the orbit (fig. 44 *A* and *B*). Interestingly enough the illustration from Nélaton's work on giant cell tumors published in 1860 shows a lesion of the upper jaw, and the picture demonstrates clearly the relation of the tumor to the ethmoid bone and the inferior nasal concha. We have reproduced this illustration in this article (fig. 46).

Giant Cell Tumors of the Lower Jaw.—Lesions in the mandible show a preference for the area between the symphysis and mental foramen. Occasionally one is located at the ramus. This unique distribution of these tumors is readily comprehended when the process is related to intracartilaginous ossification.

Unfortunately little regard has been paid in either the literature or the clinics to the exact location of giant cell tumors in the head. All the available cases studied by us support the belief that the origin of the pathologic process involved is at the sites of bone formed from cartilage and related to the normal resorptive process of bone by osteoclasts which takes place in the histogenesis of these bones. The predominant location of the giant cell tumor in the epiphysis of the long bones, it was seen, was in favor of this view. The fact that the membrane bones of the skull are not involved by either bone cysts or simple giant cell tumors confirms it.

EPULIS

The giant cell epulis of the jaws affords a strenuous proving ground to the concept of giant cell tumor advanced in this paper. For apparently in this group of benign lesions which occur on the gums and about the teeth there is no temporary bone undergoing resorption to stimulate the osteoclastic proliferation. Yet the characteristic giant cell in giant cell tumor is often described by the name of epulis, and under the microscope the basis of such terminology is plainly evidenced by the numerous large giant cells found in these growths.

Varieties.—Under the low power, the presence of stratified epithelium growing downward into the tumor from the mucous membranes of the gum must be relied on to differentiate many of these growths from

Fig. 46 (from Nélaton: *Tumeurs benignes des os*, 1860).—Illustrations of a tumor arising in the ethmoid bone and presenting through the antrum into the maxilla. The resection of the jaw shows nicely the location of the tumor in the turbinates, which are derived from cartilage. (The capital letters of the alphabet were used by Nélaton to refer to normal structures, the smaller letters to the neoplastic features. Their keys have been omitted because of their irrelevancy here.)

the typical giant cell tumor (fig. 47 *A* and *B*). The giant cells are of the usual multinucleated type and differ from those in the giant cell tumor of the long bones in no important detail. In the stroma of the epulis there is a tendency for a fibrous modification or a leukocytic infiltration to take place, and in special areas new bone formation of the fibro-ostosis type, such as is seen at the margins of the giant cell tumor and in the bone cyst, are frequently seen. These islands of bone are typical osteoid spicules with osteoblasts applied to their surface.

Fig. 47 (nos. 26824 and 36458).—Epulis of the giant cell type on the upper alveolar border. *A* illustrates the gross, and *B*, the microscopic. The giant cell areas are some distance from the mucous membrane and do not show well in this picture.

The foregoing description, however, is varied markedly in the so-called fibroid epulis. Here under the microscope, the tumor is practically always without giant cells. When these occur, they are sparse and small (fig. 48). The stroma is spindle and fibroblastic and in some places it is loose and edematous forming small evacuated cysts. In other places the fibroblasts are being transformed into osteoblasts which are laying down the intercellular substance of osteoid tissue. At points this

osteoid tissue is converted into true bony spicules of the same type seen in osteitis fibrosa. Organized hemorrhage is also present.

Microscopic analysis, therefore, divides epulis into a giant cell variety which is practically indistinguishable in its fundamental histology from giant cell tumor and a fibroid variety, which is the exact homologue of osteitis fibrosa. There are only minute variations such as a slight modification in the morphology of the giant cell in the first class of epulis and the tendency of the second class of epulis to be a solid structure

Fig 48 (no. 23768).—Photomicrograph illustrating the fibroid type of epulis. Note the resemblance to osteitis fibrosa.

rather than a thin walled cyst. The conclusion that we are dealing with the same type of pathologic process here as in the cyst and the giant cell tumor in the long bones is unavoidable. Clinically and in the gross, however, the epulis is found only along the alveolar borders of the upper and lower maxillae which are membranous bones, and it is a periosteal rather than a medullary lesion.

These two facts constitute an apparent exception to the rule that giant cell tumor and its healing phase, osteitis fibrosa, always occur in the medulla of intracartilaginous bone as a consequence of a dysfunc-

tion in the normal osteoclastic resorption of this type of bone. The belief that the giant cell tumor is an exaggeration of such osteoclastic activity in the resorption of temporary bone, advanced throughout this paper, contests such an exception to the general rule, and demands that epulis be brought into intimate relationship with a normal osteoclastic hyperplasia.

Origin.—At the outset it is necessary to exclude from a diagnostic standpoint a large number of the cases usually classed as epulis. Many extraneous lesions such as hemangioma, fibroma, fibrohemangioma and fungating ulcers of infectious origin are erroneously placed in this category on the insufficient grounds that they occur on the gums. When this group is restricted on microscopic grounds to the lesions already described under the giant cell and fibroid epulis, a clinical entity is obtained which is more readily analyzed.

Epulides of this restricted category have been shown beyond peradventure to be periosteal in origin. Bloodgood³³ has shown that the lesions arise from the alveolar dental periosteum. They may arise either under the mucous membrane of the gum immediately surrounding a tooth or from the interior of the root socket itself. Besides this close association with the periosteum of the teeth, they occur only at the alveolar borders of the maxilla in the regions extending from the first molar on the one side to the first molar on the opposite side. An epulis practically never occurs behind or fastened to the root of the last molar and rarely at the site of any of the permanent molars. This point was emphasized by Scudder³⁴ in a review of 178 cases compiled from various clinics. They are most frequent near the canine and bicuspid teeth. Clinically, this relation to the teeth is further emphasized by the symptoms of the patient who gives a history of a carious tooth or some other dental irritation. The patient generally refers to the growth in its early stages as a gum boil, but the advanced stages may show a tremendous overgrowth of tissue protruding over the jaw and outside of the oral cavity. The growth of the epulis is outward and practically never invades the bone but pushes upward through the gums in the crevices about the teeth or in a fossa where a tooth has been pulled. The overgrowth and increase in size is never rapid until the tumor has escaped the confines of the alveolar border and is proliferating over the margins of the gum. The patients are most often children or young adults.

It is a consideration of these clinical features of epulis that gives a clue to the pathologic changes in this disease. First, they arise only

33. Bloodgood, J. C., on Epulis, Bryant and Buck: *American Practice of Surgery* 6:818, 1909.

34. Scudder, C. L.: *Tumors of the Jaws*, Philadelphia, W. B. Saunders Company, 1912.

about the periosteal borders of certain teeth. Second, they practically never occur at the site of the molar teeth. Third, they expand outwardly and proliferate only after escaping the alveolar border. Fourth, they occur most frequently in children (not infants) and young adults. Again the age incidence and the site of the lesion are invaluable in disclosing the nature of the pathologic process. The unique features of the age limits and the failure of the epulis to occur about the molars relates these lesions to the deciduous teeth. For unlike all the other teeth the molars make only one appearance and that is a permanent one. If epulis can be related to the normal process of shedding the deciduous teeth which begins at the age of 6 and extends to the thirteenth year, the histogenesis of this process should explain the nature of the epulis and correlate the pathologic changes in this lesion with those in other giant cell tumors. This expectation is fulfilled when a study is made of the embryology of the teeth and the histologic process by which they are shed. Here the hyperplasia of osteoclasts seen in giant cell tumor is duplicated by an analogous process, in which there is a proliferation of odontoclasts that are instrumental in loosening and dissolving the roots of the deciduous teeth.

In more detail the histology is as follows: The anchorage of the deciduous teeth is by means of a thin layer of dental cement or cementum which surrounds the roots and is invested by a periosteal coat (or pericementum) which forms at once the outward coat of the roots and the periosteum of the jaw uniting the one to the other. The pericementum stops at the neck of the tooth and forms an annular thickening in conjunction with the dense connective tissue of the gum that is known as the circular dental ligament. The cementum itself is membranous bone and differs in no essential respect from this type of bone found elsewhere in the body. At about the age of 5 years odontoclasts arising from the pericementum or periosteum of the root proliferate and absorb the cementum of the roots of the deciduous teeth and thus open the way for the eruption of the permanent teeth (fig. 49).

About the roots of the deciduous teeth, therefore, there is a periosteum which is normally endowed with the power of osteoclastic hyperplasia. This osteoclastic hyperplasia is a normal occurrence after the age of 5 and is nature's provision for shedding the deciduous teeth. The process is analogous to the osteoclastic hyperplasia that occurs in the ends of the long bones and in the cartilaginous bones of the skull and is the natural method for the absorption of cartilaginous bone. The deciduous teeth, therefore, are in part like cartilaginous bone in that both are temporary bony structures and the pathologic process of giant cell tumor arises in connection with either, in one case giving origin to epulis and in the other the typical giant cell tumor of the long bones.

The fact that there is a fibroid type of epulis just as there is osteitis fibrosa in relation to giant cell tumor confirms this view. The fibroid epulis is the evidence of the healing reaction of the periosteum about the lesion. This healing reaction, like that everywhere in the periosteum

Fig. 49 (after Arey. *Am. J. Anat.* 26:315, 1919-1920).—Giant cell osteoclasts about the roots of the deciduous teeth of young pigs. *ocl.* indicates giant cell osteoclasts; *mtz.*, matrix of teeth roots and *obl.*, osteoblasts.

and subperiosteal layers of bone, is an efficient defense against osteoclastasia or giant cell tumor. We have seen that it is capable of arresting a giant cell tumor or bone cyst in the shaft of a bone. At the epiphysis, however, where periosteum and cortical bone are deficient,

the giant cell tumor is progressive and breaks through. In the same way, in regard to epulis, the fibroid reaction (or as we choose to call it fibro-ostosis) is an efficient barrier to the tumor. It practically never invades the body of the jaw unless there has been undue trauma or some other factor. The ability of the epulis to progress and to proliferate over the gum, however, is due to the fact that periosteum ceases at the surface of the tooth, and it is through this gap about the teeth that the epulis erupts.

There are few other places in the body, to our knowledge, in which the periosteum is endowed normally with such osteoclastic proliferation as it is here at the alveolar border, although it is true as is demonstrated in the absorption of callus after fracture that all periosteum has some osteoclastic power. The unique situation, therefore, of epulis is readily comprehended. These tumors are connected with the shedding of the deciduous teeth, and the age incidence of them is related to the eruption of the permanent teeth as is shown in table 12.

TABLE 12—*Age Incidence of Epulis in Relation to Eruption of Permanent Teeth*

Age of Eruption of Permanent Teeth *		Age Incidence of Epulis †	
First molars	6th year	5 to 10 years	6 cases
Two central incisors	7th year	10 to 20 years	17 cases
Two lateral incisors	8th year	20 to 30 years	7 cases
First premolars	9th year	20 to 45 years	9 cases
Second premolars	10th year		
Canine	11th and 12th year		2 cases
Second molar	12th and 13th year		
Third molar	17th and 25th year		

* Gray's Anatomy, ed 21, 1924, p 1134

† All patients were over 5½ years and under 45 years of age. No lesions occurred at the site of the third molar.

It will be seen that there is a latent period or lag between the appearance of epulis and the shedding of the teeth. In other words there is an elapse of time between cause and effect which is due to the slow and benign course of these lesions. But the important point is that the epulis does not occur before the age of 5, and this is due to the fact that the permanent teeth do not begin to erupt until the age of 6. Instead of being an exception to the rule that giant cell tumor follows on a normal proliferation of osteoclasts, the epulis, therefore, presents valuable evidence in confirmation of this view. These lesions are related to a normal proliferation of the odontoclasts, and the process is best termed odontoclastasia which avoids the confusing miscellaneous group of conditions that for years have been carelessly thrown together under the term of epulis.

XANTHOMA

The view that the giant cell tumor arises as an abnormal phase in the osteoclastic resorption of cartilaginous or temporary bone demonstrates its usefulness when applied to the pathologic changes in the giant cell tumors of the xanthoma group. For here this conception enables

us to disprove the current endothelial and granulation tissue theories of these growths and to split off for the first time a clinical and pathologic entity from this chaotic group of lesions.

Varieties.—Since Lebert,³⁵ in 1845, introduced the term xanthos to denote a group of yellow fibrous tumors, a large and miscellaneous collection of entities has accumulated under that heading. A group of skin lesions under the names of xanthoma palpebrarum, xanthoma diabeticorum and xanthoma multiplex may be set aside here because giant cells are absent and untypical of this series. While containing lipid pigments, blood pigment is usually wanting in these lesions. The xanthomatous tumors connected with the joints and tendons, however, frequently contain typical giant cell areas, and are related to the group of skin lesions mentioned only by their characteristic yellow color which has been shown definitely to be due to blood pigment or lipoids and hence nonspecific. Cells related to these lipoids and containing cholesterol have been referred to in the literature as foam cells and occur just as indiscriminately in this series of tumors as does pigment, being less frequent, but equally nonspecific. These foam cells also accompany at times typical giant cell areas in this collection of growths, and the presence of these cells in otherwise typical giant cell tumors of the long bones has led to the connotation of xanthosarcoma of bone by some authors.

Writers on the subject of xanthomatous tumors are agreed that this group comprises neither a clinical nor a pathologic entity. But since the giant cell areas have been viewed as nonspecific granulation tissue and both pigment and foam cells have been proved to be nonspecific, a criterion has been lacking wherewith to begin the analysis of this group of lesions into separate entities.

Nevertheless, since the time of Chassaignac³⁶ in 1852 and Billroth³⁷ in 1868, clinical peculiarities in regard to giant cell tumors of the tendon sheaths have repeatedly caused them to be set apart in this xanthoma group. More recently Tourneux³⁸ in 1913, Beekman³⁹ in 1915, Broders⁴⁰ in 1917, Garrett⁴¹ in 1924 and Mason and Woolston⁴² in

35. Lebert: *Physiologie et pathologie*, Paris, D. Baillière, 1845, vol. 2, p. 120.

42. Mason, M. L., and Woolston, W. H.: *Isolated Giant Cell Xanthomatic Tumors of the Fingers*, *Arch. Surg.* **15**:499 (Oct.) 1927.

1927 have emphasized the tendency for these tumors to occur on the hand about the fingers and on the foot and about the ankle. Although the exact limits of the group were pathologically ill defined, Mason and Woolston ⁴² were able to collect 144 cases including eight of their own, placed in this class with reasonable assurance on the grounds of their characteristic location and peculiar histology. The clinical summary by these authors shows that the sexes are about evenly affected, that adults with an average age between 35 and 40 predominate, and that the size of these firm yellow tumors ranges between that of a pea and that of an egg. The course of the disease is typically benign but protracted

(average duration four and one-fourth years), while trauma as an etiologic factor is present in from 30 to 60 per cent of the cases.

We have restudied this group of tumors and have had the privilege of checking the studies made by Garrett ⁴¹ in this laboratory in 1923 who reviewed 196 lesions of the joints, bursae, tendons and of the subcutaneous tissues. Our restudies with over 100 additional cases in the same groups accumulated since that time permit a segregation of twenty-seven lesions with a xanthic color composed of fairly typical giant cell areas, and the group thus histologically restricted presents more forcibly certain clinical and pathologic peculiarities.

As shown in table 13, eighteen of the twenty-seven lesions were located on the fingers at the metacarpophalangeal or interphalangeal

joints, and most of these were on the flexor surface. The remainder with few exceptions were elsewhere on the hand or about the foot and ankle. This predilection of the tumors for the tendons in special regions only is of more than passing significance.

Not only are the localities involved unique, but the histologic structure of these lesions is equally striking. Fibrosis of a marked degree akin to the spindle cell variant of giant cell tumor or to the fibroid type of epulis predominates the stroma about the giant cell areas. This

Fig 50 (no. 42995) —Photomicrograph showing the high power of a giant cell xanthoma of the tendon sheaths. Note the network of intercellular substance, the giant cells and the numerous round cells. A few larger cells resembling cartilage cells are seen among the fibrous network.

fibrous tissue takes an unusually brilliant pink stain with hematoxylin and eosin and forms a peculiar lattice work in special areas enclosing cells that resemble cartilage cells (fig. 50). Giant cells of the usual epulis type, large and multinucleated, are numerous, and frequently average more than 30 to a low powered field. They are embedded in the usual round cell stroma typical of giant cell tumor, and conspicuously not the round cell infiltration seen in granulation tissue. Occasionally,

the foam cell characteristic of other types of xanthoma is present, but this type of cell has also been observed in 5 per cent of the giant cell tumors occurring in the long bones.

Under the microscope, pigment is a conspicuous feature of most of these tumors. As Smith⁴³ showed by his studies in this laboratory, this pigment is old blood pigment and gives the typical iron reaction.

Since we reject on histologic grounds the current granulation tissue theory of these lesions, it is necessary for us to demonstrate a connection between these tumors and some bony or cartilaginous structure. Heretofore attempts to establish such a relationship have failed, since tendons attach to the fibrous layer of the periosteum and bone only at their distal ends and the tumors under discussion are found not at this point, but in a more proximal position within the tendon sheaths.

Origin of Xanthoma of the Tendon Sheaths.—Fortunately there was available in the laboratory an important clue. A giant cell tumor of the patella was on record (table 7). Seven such tumors of the patella recorded as variants of either the bone cyst or the giant cell tumor have been reviewed by Cole,⁴⁴ and a personal communication from King and Towne⁴⁵ described a similar tumor of the patella the report of which has been published in the ARCHIVES OF SURGERY. The microscopic appearance of these tumors of the patella resembles the giant cell tumor of the tendon sheaths in regard to the large amount of pink-staining fibroid material. Still more important is the fact that the location of these tumors resembles the site of origin of similar tumors in the xanthoma group, in that the patella is embedded in a tendon, being a true sesamoid bone derived from cartilage.

The immediate inference suggested is that the giant cell tumors of the tendon sheaths arise in the sesamoid bones. The fact that these bones are derived from cartilage brings this inference into line with the conception of giant cell tumor pointed out in this paper and the fact that these sesamoid bones occur more frequently in the tendons of the fingers coincides with the location of these tumors described clinically.

A review of the embryology and anatomy of the sesamoid bone occurring in the human body supports the view that the giant cell tumor of the tendon sheaths arise from these bones. These bones must be regarded according to Thilenius⁴⁶ as integral parts of the skeleton

phylogenetically inherited. Bradley⁴⁷ has shown that embryologically these bones are cartilaginous buds separating off from the joint side of the future bone just beneath the flexor tendon (fig. 51). The work of Pftzner⁴⁸ has shown that the sesamoid bones are most frequent on the first, second and fifth digits of the hand and foot at the metacarpophalangeal or the metatarsophalangeal joints, but that they may occur at the site of these joints or the interphalangeal joints in all of the fingers and toes. Other, but more unusual, sites are in the tendons about the elbows, knee or ankle and in the tendon of the psoas muscle at the pubis

Fig. 51 (after Bradley: *Anat. Anz.* **28**:528, 1906).—Sketch showing the development of a sesamoid bone on the flexor side of a digit in a pig embryo 52 mm. long of forty days' gestation. The sesamoid bone, preformed in cartilage, is seen budding from the joint side of the distal phalanx.

or occasionally in the gluteus maximus near the head of the greater trochanter (table 14 and fig. 52).

the literature, all of those cases having typical giant cell areas were found to coincide in location with the sites of sesamoid bones. The occurrence of the sesamoid bones most frequently on the flexor surfaces of the fingers of the right hand is duplicated by these tumors. Mason and Woolston⁴² in their review of 144 cases found the flexor surfaces of the fingers of the right hand most frequently affected, sixty-four of seventy-four tumors occurring on the flexor surfaces. On the lower extremities there is a similar coincidence in location, the xanthic giant cell tumors here occurring about the malleoli at the ankle and along the toes at the site of sesamoid bones. In the cases reported in the literature in which these xanthic tendon sheath tumors do not occupy the site of sesamoid bones, the microscopic reports show that they do not have the typical giant cell structures⁴⁹ and that they belong more properly to the fibrohemangiomas, fibromas or ganglion class, a point of

view confirmed by our studies of more than 300 cases of this variety in the surgical pathologic laboratory.

The most convincing evidence that the sesamoid bones are the source of origin for these growths, however, is presented by the histology of the tumors themselves, for some vestige of the original structure of the sesamoid bones is usually visible under the microscope.

Special study on this point reveals the fact that the pink-staining network of tissue observed in the sections is the remains of white fibrocartilage from which tissue the sesamoid bones are known to be derived. The presence of this stroma containing cartilage cells confirms the origin of these tumors from the sesamoid bones. In several cases the calcification of this cartilage and transformation to bone were observed in the sections (fig. 53).

49. Since this paper was written the article by R. S. Rowland on "Xanthomatosis" has appeared (Arch. Int. Med. 42:611 [Nov.] 1928). The erosion of the skull bones described by him is due to the tumors in the dura, and the few giant cells observed are phagocytizing dead bone, and are secondary to, rather than primary in, the xanthomatous tumors of the dura. Sections sent to the authors through the courtesy of Dr. Rowland do not show giant cell tumor.

Fig. 52 (after Plützner: *Morphol. Arb.* 1:517, 1892).—Anatomic preparations showing sesamoid bones in most of the localities in which they occur on the hand and foot and at the knee and elbow. Sesamoid bones occurring about the ankle are not shown in this illustration.

Fig. 53 (no. 31888).—Tumor of the sesamoid bone on the great toe. Bone derived from cartilage surrounded by giant cells is shown in the high powered photomicrograph. This tumor of the xanthoma group became infected and showed a healing reaction similar to osteitis fibrosa.

The peculiar yellow color of these tumors that has attracted so much attention differs from the deeper russet color of the giant cell tumor of the long bones because of changes in the blood pigment associated with age. These xanthic tumors have a much longer duration of symptoms (fifty months average duration as compared with fourteen months for giant cell tumors of the long bones), and their limited size is due to the small size of the bones affected and the resistance of the fibrous encapsulation, derived from the tendon sheaths. Adjacent bones are eroded on the side opposite the tendon sheaths, however, as is frequently recorded in the operative notes from many different clinics. In these small bones, compact bone, which promotes ultimate healing, is wanting, and a slow protracted course is the result.

From the foregoing it is seen that giant cell tumors of the tendon sheaths, which have long been erroneously classed under the heading of xanthoma are in reality tumors of the sesamoid bones, rather than of soft part structures. These sesamoid bones which are derived from fibrocartilage when affected by giant cell tumor emphasize again the relation of osteoclastic proliferation in bone newly formed from cartilage to the giant cell tumor.

The Xanthoma Variant of the Giant Cell Tumor of Bone.—Xanthoma or foam cells appear occasionally in giant cell tumors of the long bones. In the series of giant cell tumors (exclusive of those of the tendon sheaths) reviewed in this paper, these characteristic foam cells were found in only nine cases (fig. 54 A). These cells never predominated the picture and were relatively scarce, the tumor in the gross resembling the ordinary giant cell tumor. Although a case of xanthosarcoma of bone as described by Ewing⁵⁰ has never been observed in our series, we have noted foam cells in two cases of osteogenic sarcoma (fig. 54 B). Both of these cases have been reported in the literature, one by Goforth⁵⁰ and the other by Stone and Ewing,⁵¹ with the diagnosis of malignancy in giant cell tumor. No note was made on the presence of the foam cells by these authors, but we observed them in a restudy of the sections.

A review of the nine cases of giant cell tumor with foam cells brings out nothing of significance other than the fact that the bone shell is perforated in these instances. The histology resembles that of the typical giant cell tumor without xanthoma cells, and clinically there are no unique features. The presence of two recurrent giant cell tumors and two so-called metastatic giant cell tumors in this series of xanthoma

⁵⁰ Goforth, J. L.: Giant Cell Tumor of Bone. Arch. Surg. 13:846 (Dec.) 1926.

⁵¹ Stone, W. S., and Ewing, J.: An Unusual Alteration in the Natural History of a Giant Cell Tumor of Bone. Arch. Surg. 7:280 (Sept.) 1923.

variants is to be associated with the perforation of the bone shell by such lesions and not with an increased malignancy. The xanthoma cells are the results of the inclusion of lipoids from the soft parts about the tendons where the tumor is infiltrating, and obviously it is the extent of the destruction of the bony shell of the tumor and not the chance presence of foam cells that has clinical significance.^{51a}

Giant Cell Tumors of the Soft Parts.—Because of their relation to the sesamoid bones a brief note is included here on so-called giant cell tumors of the soft parts. The records of only three such cases are available to us at this time. Two of these cases are from the surgical pathologic laboratory, and one is from the literature. In all of these cases we were able by location to relate the tumors to preceding bone.

Fig. 54 (nos. 38238 and 40766).—Photomicrographs showing *A*, xanthoma cells in a typical giant cell tumor in the lower end of the radius, and *B*, xanthoma cells in an osteogenic sarcoma in the upper end of the tibia. The bony shell about the tumor was perforated in both cases.

The condition in the first case was diagnosed clinically as a recurrent mixed tumor of the parotid gland (fig. 55). The patient was a white woman, aged 23, with a tumor near the left ear of three years' duration. An incomplete removal of the growth had been performed eighteen months previously, and at the second operation a tumor the size of a

51a. The connection between the foam cells in these tumors and the lipoids derived from the tendons has been confirmed by a study recently called to our attention and published by Kusnetzowski (Virchows Arch. f. path. Anat. 263:205, 1927).

hen's egg was found wedged in between the mastoid process and the angle of the jaw about the stylomandibular ligament. The pathologic diagnosis at that time was xanthoma of the parotid gland. A restudy of this case in this laboratory four years afterward showed it to be a giant cell tumor of the styloid process arising from the lower portion of the bone which has a separate center of cartilaginous ossification, and to which the stylomandibular ligament is attached. Thus the giant cell

Fig. 55 (no. 35631).—Photomicrograph of a so-called xanthomatous tumor of the parotid gland. This tumor proved to be a giant cell tumor with foam cells arising from the styloid process of the temporal bone.

tumor tissue was related to cartilaginous bone and the foam cells in the tumor associated with a ligamentous structure.

The other two cases are related by location to sesamoid bones. One of these was described by Mallory,²⁸ who observed, "Foreign body giant cells are sometimes produced in such large numbers in reparative lesions not connected with bone that they may suggest a so-called giant cell sarcoma. An illustration of such an appearance is given for comparison. The giant cells followed some destructive lesion of the fat tissue over

the pubes (plate 28, figure 4)." This most extraordinary location coincides with the site of a sesamoid bone in the tendon of the psoas muscle where it glides over the pubic bone. Unfortunately, the unusual site of the lesion did not excite the curiosity of the author.

The last case is similar to this one of Mallory's in that it occurred in the head of the gastrocnemius muscle at the site of a sesamoid bone. Under the microscope the remains of the sesamoid bone were clearly visible, although the tumor had been diagnosed five years previously as a probable sarcoma of the soft parts.

While we have observed giant cells about bone displacing calcified necrotic tissue in tumors of the soft parts, as in the breast, we have never found typical giant cell tumor in such a locality, and we doubt that this tumor ever occurs under such conditions.

SUBPERIOSTEAL GIANT CELL TUMORS

Beside the giant cell tumors of the skull, of the alveolar borders and those of the sesamoid bones, another group of lesions assume a location significant for the interpretation of the pathologic nature of giant cell tumor. This group is the subperiosteal giant cell tumor which occurs in the shaft of the long bones and which presents certain unusual features that bear directly on the etiology of the lesions that we have been considering.

The subperiosteal giant cell tumor comprises a group of extremely modern recognition. Although periosteal giant cell tumors are described in older case reports, such cases on careful analysis prove to be typical giant cell tumors that have perforated their bony shell and grown extra-cortically with a fibrous reaction overlying them. The major portion of such tumors lies within the bone. What is here described as a subperiosteal giant cell tumor is a lesion beneath the periosteum that does not invade the bone to any significant extent. Only four such cases are in this collection, and lesions described of a similar nature are rarely reported in the literature. There is one excellent report by Cone⁵² who described it as an ossifying hematoma. In this contribution the author who has long devoted himself exclusively to the study of pathologic changes in bone had the perspicacity to observe that "osteitis fibrosa, hemorrhagic osteomyelitis and giant cell tumor of bone have their representations in the microscopic pathology of this ossifying hematoma."

The data for the four cases comprising this series are summarized in table 15. In addition to the unique location of the lesions beneath the periosteum of the shaft the striking features brought out are: (1) the short duration of the symptoms (from two to eight weeks); (2) that trauma was the usual initial symptom and (3) that all cases have been recorded since January, 1926.

52. Cone, S.: Ossifying Hematoma, *J. Bone & Joint Surg.* **10**:474, 1928.

Evidently the diagnosis of subperiosteal giant cell tumor is dependent on an early roentgen examination of the patient following trauma. In the roentgenogram the periosteum is raised by a tumor casting little or no shadow which resembles a subperiosteal hematoma (fig. 56). At the operation an extremely thin capsule or shell of bone described by most operators as a blue dome presents itself, and when incised a cystic cavity containing blood is found. Tissue removed from this cavity and examined under the microscope shows a structure of typical giant cell areas intermingled with osteitis fibrosa. In every case there was uncertainty whether the condition should be termed a cyst or a giant cell tumor (fig. 57).

The explanation of these lesions is illuminating, their short duration, their clear relation to trauma and their appearance under the microscope yielding valuable information in regard to the sequence of the pathologic

TABLE 15.—*Subperiosteal Osteoclastasia* *

* All lesions were observed since January, 1926.

events. In these cases it is clear that trauma and hemorrhage followed by separation of the periosteum (with a subperiosteal osteogenic layer of tissue) are the initial pathologic events. In the cortex beneath, a disturbance in the periosteal blood supply must occur, and in the periosteum above, some sort of healing reaction is sooner or later stimulated. The result is the mixture of giant cell areas and osteitis fibrosa which are seen under the microscope. That both factors are concerned in healing in this region is exemplified by callus formation and its resorption which forms commonly after most fractures. It is well known that an exuberant callus laid down by the periosteum will be eventually resorbed by osteoclastic activity. In the group of lesions under discussion the osteoclastasia that arises as a result of injury is rapidly regressive. The healing power of the underlying cortical bone and the overlying periosteum is evidently sufficient to heal over any abnormal activity of the osteoclasts. For this reason the duration of symptoms is short, and unless the patient comes under observation soon after injury and a roentgen examination is made, the lesions regress unrecognized, and disappear entirely or in unusual cases persist as a healed exostosis.

Our interest in these lesions is in the relation of hemorrhage following trauma to osteoclastasia. Evidently hemorrhage and a disturbance of the normal blood supply of bone act as a stimulus to the proliferation of osteoclasts and may in some cases lead to an abnormal osteoclastasia, or giant cell tumor. This conclusion means that in the study of the blood supply of the region of the epiphysis and in the factors that may disturb its normal functioning is to be found an explanation of the origin of the giant cell tumor. Some imbalance must arise in the rela-

Fig. 56 (no. 38372).—Anterior and lateral x-ray views of subperiosteal osteoclastasia occurring in the shaft of the ulna. The lesion is eight weeks old.

tionship between the proliferation of osteoclasts and the reaction of fibro-ostosis, for apparently it is these two processes that participate in the healing of bone after injury and hemorrhage.

ETIOLOGY OF GIANT CELL TUMOR

It is much easier to discuss the etiology of tumor in terms of so-called etiologic factors than it is to point out the initial event and a subsequent unbroken chain of histologic consequences. For this reason,

the literature abounds with references to the etiologic factors of trauma and hemorrhage in the production of giant cell tumor and bone cysts. Konjetzny,²⁰ Lubarsch⁵³ and Pommer⁵⁴ are among those of the German school that have attempted to trace the bone cysts to medullary hemorrhage following trauma. We are in accord with these authors in placing

Fig. 57 (no. 39293).—Subperiosteal osteoclastasia of two weeks' duration. The photomicrograph shows the giant cells in relation to a newly formed blood cavity. Young fibrous tissue is attempting to repair the lesion. Microscopically, the tissue represents a borderline between giant cell tumor and osteitis fibrosa.

54. Pommer, G.: Zur Kenntnis der progressiven Hæmatom und Phlegmasieveränderungen (H. v. Haberers), *Arch. f. Orthop. u. Unfall. chir.*, 1920, vol. 17.

trauma in a primary position in the production of these lesions. An attempt will be made, however, on the grounds of the embryologic observations pointed out earlier, to show just how trauma acts histologically in producing the bone cyst and the giant cell tumor.

Relation of Osteoclastasia to the Interruption of the Periosteal Blood Supply.—In the embryo, permanent compact bone is laid down by the perichondrium or subperiosteally, and, as we have seen, this cortical bone is a stronghold for the healing reaction of fibro-ostosis after injury. For nourishment, this bone is partially dependent on the periosteal blood supply. In young adults, this subperiosteal region is an extremely vascular and active tissue, and new bone formation proceeds here more rapidly than elsewhere. On the other hand, the most primitive cancellous bone in the medulla which undergoes reconstruction even in young adults by osteoclastic activity to form the medullary cavity is nourished by vessels in the medulla, the origin of which is from the nutrient artery. This cancellous bone of the epiphysis is supplied from vessels which anastomose around the joint, the diaphyseal, the metaphyseal and the epiphyseal, but as pointed out by Poland²¹ and shown in injected specimens (fig. 58) by Lexer,⁵⁵ these vessels concerned with the major portion of the nutrition of both epiphysis and metaphysis pursue a periosteal and transcortical route.

The significance of this vascular arrangement in the origin of osteoclastasia has been implied in the discussion of subperiosteal giant cell tumor following trauma. The evidence in that group of lesions points to the fact that a vascular disturbance following trauma is a primary factor in the etiology of giant cell tumor.

A unique observation in regard to the site of early lesions of progressive osteoclastasia must now be recalled. Early giant cell tumors in the epiphysis (with a short history of trauma from two to six months previously) practically always assume an asymmetrical and subcortical location. In other words the giant cell tumor, and also the early bone cyst arise at a point just beneath the traumatized area of the cortex. This was pointed out in the study of the x-ray pictures and the gross specimens of these lesions and is again illustrated in the case shown in figure 59. Here the lesion is near the surface of the bone in one of the condyles of the femur. There was a definite history of trauma only two months previously as compared to the average duration of symptoms of fourteen months in giant cell tumor. The import of this subcortical location of the initial epiphyseal lesion has apparently been overlooked heretofore because the giant cell tumor during a later stage enlarges centrally at the expense of cancellous bone rather than out-

55. Lexer, E.: Die Entstehung entzündlicher Knochenherde, Arch. f. klin. Chir. **71**:1, 1903.

wardly against the more resistant cortical bone. The realization that the classic early giant cell tumor of from two to six months' duration practically always gives a history of trauma and shows a lesion sub-cortically at one side of the epiphysis furnishes an important clue to the etiology of this tumor. The site of the early lesion in relation to trauma suggests the cause of the imbalance in bone formation and bone destruction already referred to and demonstrates the sequence of events leading to progressive osteoclastasia.

Fig. 58 (after Lexer: *Arch. f. klin. Chir.* 71:1, 1903).—Injected specimens showing the epiphyseal blood supply in the long bones. The femur and tibia are represented.

Because of the prominence of the club-shaped epiphyseal region the cortical or outward edge receives the brunt of the trauma in this locality. This trauma acts mainly on the cortex in relation to its periosteum, avulsing the latter and interrupting the blood supply of the cortical bone. Normal vascular channels are thus supplanted by a subperiosteal hematoma. The effect of this interruption of the periosteal blood supply is to render inactive the cortical bone on this side of the epiphyseal end,

and the normal healing powers of this portion of the bone are suspended. The medullary circulation in the region of the epiphysis must take up an increased activity and by establishing new channels it works its way around the injured area to undertake the work of repair.

This increased function of the medullary blood supply during the interruption of the periosteal circulation can take place only after osteoclasts have opened up the channels in bone for the budding capillaries (for this we have seen is the normal order in histogenesis).

Fig. 59 (no. 20115).—Giant cell tumor of two months' duration in the epiphysis of the femur. Attention is directed to the subcortical location of the lesion and the staining of the surrounding tissue by old blood. The specimen illustrates the typical site of origin of the giant cell tumor.

But this increased osteoclastic activity in an area in which they are already unusually active in the rôle of new bone construction, occurs just at that time when unnourished cortical bone is undergoing necrosis. An imbalance is thus created between bone destruction by osteoclasts and new bone formation that would normally proceed from the reactive cortex were its circulation intact. The defensive reaction of cortical bone, therefore, is suspended while bone destruction by osteoclasts is at its height. This imbalance results in an unchecked hyperplasia of

the osteoclasts and produces a tissue characteristic of giant cell tumor and the early phase of osteitis fibrosa or bone cysts.

In the metaphysis, the reactive cortical bone which is thick and vascular, is apparently capable after a time of overtaking the osteoclasts. In the epiphysis, however, bone destruction seems to proceed at a faster rate than the thin cortical bone in this region can overtake. The result is an arrested lesion or bone cyst in the metaphysis, and a progressive or unchecked lesion in the epiphysis which is known as the giant cell tumor. Even in the epiphysis, however, the balance can be restored if surgical intervention occurs before the bone shell is too extensively destroyed. If the osteoclastic tissue is removed by the curet and cautery (and we suggest by aiding nature to collapse the bone cavity remaining), the giant cell tumor will also go on to ultimate healing.

Thus, histologically, trauma is related to the bone cysts and the giant cell tumor, not as an indefinite etiologic factor but as an initial event in disrupting the cortical blood supply which produces an imbalance between osteoclastic proliferation in the medulla and reactive compact bone in the cortex. In the etiology of these lesions individual variations in collateral circulation as well as the extent of the injury are important factors. That additional metabolic factors may enter into the production of this unbalance is shown by the analysis of multiple giant cell tumor and bone cysts presented in this paper, and the studies by Wilder^{25a} on the serum calcium and phosphorus in these conditions. It is apparent, however, from the studies recorded here that the age of the patient, the site of the injury, the rate and extent of cartilaginous ossification at the end of the bone and the nature of the blood supply in the affected regions are the predominant factors in the pathologic process of bone cysts and giant cell tumors.

When all of these factors are considered, it is apparent why both bone cysts and giant cell tumors are rare in comparison to the frequency of trauma. It must be emphasized that to have the lesions clinically, an imbalance in two normal repair processes is necessary—an unusual increase of osteoclastic proliferation and a diminution or suspension of new bone formation in an injured cortex. These two processes are always active after injury. Both fibro-ostosis (osteitis fibrosa tissue) and osteoclastic proliferation (giant cell tumor tissue) are to be seen after ordinary fractures (fig. 60) and in the healing of a subperiosteal hematoma (Cone⁵²). Only when the bone destructive phase of giant cell proliferation is in the ascendancy for a significant period do the clinical entities of giant cell tumor or osteitis fibrosa arise.

The reasons for the distribution of giant cell tumors and bone cysts in certain favorite localities can now be pointed out. We know that the most frequent site of the solitary bone cyst is in the femur near the great trochanter and in the humerus near the greater tuberosity. These

are points of trauma at the hip and at the shoulder. Bone cysts, rather than giant cell tumors form at these sites because the epiphysis in the head of the femur and the head of the humerus are shielded from trauma and enclosed in the sheltered acetabulum and glenoid cavities. Trauma, therefore, reaches the shaft side of the epiphysis and a more resistant

Fig. 60 (general pathology, no 58) —A healing fracture in a rib of a normal dog. Seven giant cells to the low power field are busy reforming the medullary cavity after callus formation. This illustrates the phase of osteoclastic proliferation in the normal healing process.

and better developed cortex of compact bone arrests these lesions after a time. On the other hand, in the lower end of the femur, the upper end of the tibia and the lower end of the radius, the epiphysis is exposed and

frequent trauma in these localities accounts for the prevalence of giant cell tumors at these points. In the upper end of the tibia, both the epiphysis and metaphysis at the tuberosity of the tibia are exposed to injury, and in this location both giant cell tumor and bone cysts occur. That these regions should be peculiarly susceptible to the trauma received is due to the active state of the bone-forming process in these localities. For, as Poland²⁴ has pointed out, "in the tibia and humerus the upper ends, in the femur and bones of the forearm, the lower ends, are in this respect (bone growth) the most active."

That it is locality alone that accounts for the difference between bone cysts and giant cell tumor can now be more clearly demonstrated. It has been pointed out earlier that the polycystic osteitis fibrosa is an earlier form of bone cyst. The short duration of symptoms, the vascularity and the giant cell areas confirm this. More important still the subcortical location of these lesions demonstrates that they have an identical mode of origin with the giant cell tumor. The infiltration of the giant cell areas by fibro-ostosis shows from the outset that they are destined to be arrested by a restoration of the balance between fibro-ostosis and osteoclastic proliferation.

It is also clear now just how pathologic fracture helps to heal a bone cyst. Not only does such an injury serve to collapse the rigid walls of the cavity, but in the area of shaft bone a fracture serves to reverse the process of circulatory disturbance already described.

The severing of the continuity of the shaft interrupts the medullary circulation and stimulates the periosteal blood supply, at the same time cutting off the nutrition of the osteoclastic tissue which receives blood from the medullary vessels. This process of circulatory changes following fracture has been ably reviewed by Robinson.⁵⁶

Embryonic Histology in Relation to Pathologic Changes.—Since the time of Cohnheim⁵⁷ in 1877, the histogenic relationship of tumor has been inferred and speculated on, much data having accumulated in support of this view. But unfortunately Cohnheim placed emphasis only on the abortive products of embryology—cell rests—rather than on the histogenic processes in themselves. For this reason no painstaking effort to correlate the embryonic histology of the bone with the pathology of the bone tumors has ever been undertaken, to our knowledge. This most fruitful field of investigation has remained practically unexplored.

In advancing the knowledge concerning malignancy no possible realm of information can justifiably be neglected. The facts are many, con-

57. Cohnheim, J.: *Geschwülste, Allgemeine Pathologie*, Berlin, 1877, vol. 1, p. 622.

nections few and hazy. Therefore, the correlation of the more fundamental facts of histogenesis, anatomy and physiology of bone, although difficult, is of first importance to the understanding of tumor formation in these structures. Perhaps at this stage of our knowledge it is even more to be desired than additional points in the clinical history. We have attempted here to bring the pathology into relationship with the more fundamental facts of histogenesis and physiology and to begin the larger undertaking of approaching tumors from this standpoint.

The primitive transformations in skeletal tissue—the stage of cartilaginous calcification, the stage of resorption of substitution bone and the final stage of permanent subperiosteal compact bone all have their corresponding pathologic significance. The function of direct bone formation from fibroblasts to osteoblasts to osteoid tissue, typical of the final stage of bone development, we have found to be instrumental as a healing reaction (fibro-ostosis) in the repair of bone and significant for the understanding of osteitis fibrosa. The function of bone resorption by osteoclasts followed by increased vascularity and the creation of medullary spaces, while a characteristic phase in the histogenesis of bone plays also a fundamental rôle in the production of giant cell tumor. And in the same way, the more primitive histogenic functions underlying the transformation and calcification of cartilage are reproduced in the pathologic process of osteogenic sarcoma. This last carries us into the realm of malignancy and sarcoma. It will form the theme of a subsequent paper.

SUMMARY

In an analysis of over 400 cases of tumors in the giant cell group a pathologic relationship was established between the bone cyst, giant cell tumor of the long bones and skull, giant cell epulis of the alveolar borders and giant cell tumors of the tendon sheaths. The usual bone cyst occurring in the metaphyseal region of the long bones of young patients was shown to be a healing phase of giant cell tumor—a conclusion based on clinical, pathologic and anatomic observations and demonstrated by an analysis of numerous transitional lesions between these two entities.

Giant cell tumors of the skull and long bones, epulides of the alveolar border, and giant cell xanthomas of the tendon sheaths were found to be fundamentally related to a transitional process characterizing the histogenesis of permanent bone, via the indirect route of substitution bone. This transition process underlying all of these tumors, as shown by embryologic studies, involves a proliferation of giant cell osteoclasts, the function of which is to initiate the canalization and vascularization of the preliminary calcified structure.

In the long bones the preliminary calcified structure, is calcified cartilage, and this is resorbed by a proliferation of giant cells in the epiphyseal region—a distortion of this proliferative process leading to giant cell tumor.

In the skull a similar giant cell hyperplasia characterizes certain cartilaginous centers of ossification, and giant cell tumors, it was demonstrated, occur only at such sites in the portions of the skull derived from cartilage and not in the membranous bones.

In epulides of the alveolar border, the temporary calcified structures are the roots of the deciduous teeth, about which giant cell odontoclasts proliferate, attacking the cementum to bring about shedding of these deciduous structures. Here again this normal giant cell proliferation forms the basis for giant cell tumors at these sites resulting in the epulis of the alveolar border.

In the so-called xanthomas of the tendon sheaths containing giant cells, the initial calcified structures are the sesamoid bones derived from fibrocartilage, and giant cell tumors of the tendon sheaths were shown to arise only at the sites in which these small bones are implanted in the tendons.

Evidence was advanced to show that the factor superimposed on this most important transitional giant cell proliferation, necessary to the production of giant cell tumor, was a disturbance of the vascular supply to these regions following trauma. But in each instance, the underlying normal histogenic function of giant cell proliferation was stressed as the essential factor, and it was pointed out that this histogenic basis necessitates the view that giant cell tumors are neoplastic and not inflammatory in origin. The importance of this histogenic conception for the analysis of other tumors was also emphasized.

THE RELATION OF THE ADRENAL GLAND TO THE TOXEMIA OF INTESTINAL OBSTRUCTION

AN EXPERIMENTAL STUDY *

R. A. CUTTING, M.D., PH.D.

NEW ORLEANS

A rather considerable volume of experimental and controversial literature on the general subject of intestinal obstruction has appeared within recent years and has served to focus the interest of the surgeon on this interesting, and often most trying, condition. Much of interest has apparently been demonstrated as to both pathology and treatment, considerably more has been surmised and hypothecated, and still more is as yet unknown. From a practical point of view the alkalosis and dehydration which occur, particularly in so-called "high intestinal obstruction," and the diminished chloride content of the blood plasma, have served as valuable points of departure for therapeutic measures, but rather obviously the correction of such abnormalities partakes of the nature of symptomatic rather than curative treatment. The treatment for certain types of obstruction by the administration of spinal anesthesia has been successfully used by many clinicians, especially in the European clinics, and is rational in that such anesthesia may be made to ascend sufficiently high to block the inhibitor control pathway to the intestine by way of the white rami communicantes and thus prevent inhibitor impulses from spreading to the splanchnic nerves, a procedure which amounts to an actual reinforcement of the motor impulses which are normally continually reaching the intestine through the motor, or vagus, nerve supply; experimentally, the correctness of this line of reasoning has been partly, at least, substantiated by the observation that splanchnic anesthesia does actually tend to overcome obstruction by increasing the number and force of peristaltic contractions. However, even the restoration of normal motor power to the wall of the intestine apparently somewhat misses the mark, for a relatively tremendous number of experimental observations have accumulated which seem to demonstrate conclusively that the essential feature in obstruction is toxemia, particularly in those types of obstruction in which there is production of a closed loop or loops or in which strangulation occurs.

Since the latter types of ileus afford the most acute problem for the clinician, and since mild toxemia is almost undoubtedly a feature of the simplest of cases, the crux of the entire mechanism of intestinal obstruc-

* Submitted for publication, March 16, 1929.

* From the Department of Surgery, Tulane Medical School, Tulane University.

tion, from the clinical point of view at least, seems to be the source, mode of production, action, nature and neutralization of the offending toxin. Any extended study of the literature on this problem carries one through a veritable maze of observations unrelated or only partly correlated at present, some of which are actually contradictory and none of which in the present state of information gives immediate promise of a complete solution of the problem. Such theories as have been advanced are only partly explanatory and are largely at variance one with another.

In general, the only definite conclusions that appear to have been reached at present are that a toxin seems to develop in the lumen and possibly also in the wall of loops of intestine proximal to an obstruction, that this toxin probably is absorbed into the blood stream, and that it is most probably responsible for the toxemia.

The presence of such a toxin has apparently been demonstrated by a number of independent investigators. Murphy and Vincent,¹ Murphy and Brooks,² and Copher and Brooks³ used the fluid contents of the lumen of the intestine above an obstruction virtually unchanged, simply putting it through a strainer or diluting it with water; the toxicity of such a fecal infusion, when injected, would scarcely seem to afford grounds for surprise, in view of its almost certain bacterial contamination. Dragstedt, Dragstedt and Chase⁴ went a step further in that they strained and partially sterilized such fluid prior to injection by heating it to a temperature of 70 C. for an hour, and they further purified it by filtering away the coagulum thus formed; sterility was preserved with chloroform and toluene which in turn were removed, prior to actual injection, by means of heat and filtration. Clairmont and Ranzi⁵ accomplished sterilization by a process of filtration through a Chamberland filter. Stone, Bernheim and Whipple⁶ and Whipple, Cooke and Stearns⁷

used the fluid contents either after heating to 60 C. for several hours, centrifugating and filtrating it, or after a process of autolysis in the presence of chloroform and toluene for a period of several days. Davis and Morgan⁸ used both the mucosa of the intestine and its contents and prepared a toxin from these substances by admixture with sodium chloride in isotonic solution, addition of toluene and chloroform, autolysis at 37 C. for from two to ten days, heating to 60 C. for thirty minutes, centrifugation and final filtration.

In addition to the foregoing methods for the preparation of toxin, which are admittedly unsatisfactory in that a conglomeration of substances other than the actual toxic principle specifically sought must have been present in all of the products thereby obtained, two noteworthy attempts have been made to prepare the toxic agent in relatively pure form.

J. W. Ellis⁹ described a method of preparing such a toxin by which he believed he had been able to obtain a relatively pure product; he considered this toxin directly responsible for the clinical observations in cases of ileus. He described the preparation of the toxin by the following steps: (1) the collection of the contents and mucosa of the intestine in 250 cc. of hot water; (2) thorough mixing and straining of this material through gauze; (3) the addition of five volumes of 90 per cent ethyl alcohol and subsequent filtration; (4) the boiling of the filtered precipitate with 100 cc. of distilled water; (5) the addition of 1 Gm. of magnesium sulphate after boiling away all traces of the alcohol left in the filtered precipitate, and the continuation of the boiling for a few minutes; (6) filtration, and the precipitation of the filtrate in five volumes of 90 per cent ethyl alcohol; (7) the filtration of this material and the drying of it in a desiccator, and (8) the dissolving, before use, of this material in from 25 to 50 cc. of water and subsequent dialyzation of this solution against distilled water for two hours.

Sugito¹⁰ carried the process a step further, and was able to isolate a supposedly pure toxin not only from the mucosa and intestinal contents, but also from the blood serum of animals with intestinal obstruction. His process of preparation of such a toxin from serum (which is virtually the same as he used in preparing toxin from intestinal loops) consists of (1) heating the latter in boiling water until coagulation takes place; (2) cooling and incubating at 38 C. with an aqueous solution of trypsin and a small amount of toluene until complete digestion of the

coagulum has occurred; (3) filtration, coagulation in boiling water and refiltration; (4) addition of one and one-half volumes of saturated magnesium sulphate; (5) filtration through heavy filter paper; (6) solution of the collected precipitate in water and dialyzation in a collodion tube to remove the ammonium sulphate, (7) and reprecipitation with five volumes of alcohol.

There seems to be a general agreement among all the investigators who have worked on the preparation of toxin from the intestinal contents of animals with obstruction that a substance can be prepared relatively easily from such contents which is not present in the contents of normal intestine, which presents fairly definite physical and chemical properties and which, when injected, preferably intravenously, into normal animals, is capable of producing a clinical picture similar to the general clinical picture of intestinal obstruction itself, and ultimately death.

The toxic principle under discussion has been shown to possess the following properties concerning which most investigators are in agreement: 1. It is soluble in water. 2. It is not destroyed by boiling. 3. It is precipitated by five volumes of alcohol and by about 60 per cent ammonium sulphate. 4. It is not destroyed by pancreatic digestion for several days. 5. It does not pass through a collodion membrane when dialyzed against distilled water. Other properties have been described, but many of them either have not been sufficiently substantiated or seem in the present state of knowledge to be of no special significance. The properties mentioned are not, of course, sufficiently definite to establish with certainty either the exact substance or even the general class of substances to which the toxin belongs. Most investigators incline toward the opinion that it is a protein split-product; Stone, Bernheim and Whipple¹¹ and Whipple, Rodenbaugh and Kilgore¹² expressed the belief that it is a proteose; Wilkie¹³ agreed with this idea; Stone¹⁴ and Gerard¹⁵ believed it to be a histamine or histamine-like substance; Ingvaldsen, Whipple, Bauman and Smith,¹⁶ after careful analysis, came to the conclusion that it is a nucleoprotein. Other suggestions which have

been made are that it is trypsin, a toxic amine, a bacterial exotoxin, an endocrine secretion similar to the parathyroid hormone, cholin, an alkaloid or a ptomaine.

When injected, a toxin prepared according to any of the methods previously described produces a typical picture which includes vomiting, tenesmus, diarrhea, dilatation of the pupils of the eyes, tremor, weakness in the hind legs, weak, rapid pulse, decreased blood pressure and, in fatal cases, death in a state of coma—a picture, as previously mentioned, that corresponds reasonably closely with the clinical picture of experimentally produced ileus.

OUTLINE OF THE PROBLEM

During the course of some experiments on ileus previously reported, I had occasion numerous times in the last several months to employ especially the methods of Ellis and of Sugito in the preparation of toxin in both rabbits and dogs, and my results in general were strictly in accord with the published results of these investigators. However, I have never been able by chemical means to isolate from the blood serum of these animals a toxin by the methods outlined by Sugito, which, when injected into normal animals, would cause their death, although I have made many attempts. Failure to accomplish this was first attributed to the rather inexplicit directions given by Sugito for deriving the substance, but after having devoted considerable time and attention to the matter and after trying many different variations of chemical technic, the statement made by Sugito with reference to his own work with the method that, in spite of the fact that he had derived his toxin from relatively large animals, he had been able to produce death only in very small ones began to acquire considerable significance as offering a fairly obvious explanation for previous failure. Reflection on these facts gradually crystallized itself into two correlative propositions: (1) either so much of the toxin must have been lost during the process of chemical preparation that the amount finally recovered was insufficient to kill animals of anywhere near comparable size, or (2) as the result of the action of the toxin in the animal with intestinal obstruction extending over some considerable period of time, certain organic changes of an undetermined nature must have so debilitated the animal that an amount of toxin sufficient either to kill it or at least to bring it to the agonal state was insufficient to kill another animal of reasonable size.

At about the same time that attempts to prepare toxin from obstructed loops of intestine had been begun, routine histologic examinations of organs of a considerable number of animals dying from the effects of obstruction were studied, and this procedure seemed fairly definitely to demonstrate that characteristic degenerative changes usually occur in the adrenal glands of such animals. Of course, the general

protective function of the adrenal glands has been recognized for a number of years. Boinet,¹⁷ in 1896 and 1897, was apparently the first to observe that animals which had undergone double adrenalectomy were more sensitive to toxic substances than normal animals, and this pioneer work has received confirmation at the hands of many more recent observers. Scott¹⁸ showed that the resistance of adrenalectomized rats to morphine, killed bacteria, and histamine was greatly reduced; Marine¹⁹ and Jaffe showed the same for standard typhoid vaccine; Belding and Wyman²⁰ for diphtheria toxin, and Crivellari²¹ for potassium cyanide, nicotine, acetonitrile and histamine. Lewis²² showed decreased resistance of adrenalectomized animals for cobra venom, curare, veratrine and morphine.

Accordingly, the problem of ascertaining the possible rôle of the adrenal glands in protecting the body economy against the toxin of intestinal obstruction was not far to seek.

OUTLINE OF THE EXPERIMENTS

The experiments that I am about to detail concern themselves with this problem. The general method was the obvious one adopted by the authors mentioned latterly in their investigation of the protective mechanism of the adrenal glands against the various other toxins enumerated. A series of animals was prepared by double adrenalectomy. A similar series of normal ones was used as controls. Half the toxin derived from the intestinal contents and mucosa of an animal with artificial obstruction was injected into an animal in the adrenalectomized series, and the other half into a corresponding animal in the normal series. The animals in both series were kept under observation until death or until the effect of the toxin had disappeared.

(a) *Selection of Animals.*—Only two of the ordinary laboratory animals are available for experiments involving survival after double adrenalectomy, the rat and the rabbit, since these are the only common laboratory animals that survive the operation of double adrenalectomy for any considerable length of time. Furthermore, since the preparation of toxin from obstructed loops of intestine involves

the use of chemical methods, it is readily apparent that the larger the amount of material available at the beginning of the process of preparation, the more likely does the obtaining of a suitable amount of the final product become. Also, it seemed highly desirable to use the same animals for the production of the toxin as for the reception of it by injection. For these reasons, it seemed desirable

Fig. 1.—Normal suprarenal cortex in the dog; low power sketch.

to use the larger animal, that is, the rabbit. Rabbits weighing from 1 to 1.5 Kg. were obtained.

(b) *Technic of Obstruction and Preparation of Toxin.*—Intestinal obstruction was produced in these animals by tying a piece of ordinary cotton tape tightly about the terminal part of the small bowel, under ether anesthesia, under

strictly aseptic conditions, and with the usual surgical technic. Animals thus prepared were returned to their cages and were kept until they became virtually moribund. It was soon found that animals thus treated survived rarely for much longer periods than forty-eight hours, and this was the time limit maintained for killing them preliminary to the preparation of toxin from their obstructed intestinal lumina. The animals were killed, the entire small intestine above the point of

Fig. 2.—Normal suprarenal cortex in the dog; high power sketch.

obstruction up to the pylorus of the stomach being excised in one piece immediately after the production of death by an overdose of ether. The mucosa and contents were removed and this material was placed in a mortar; a small quantity of clean sand was added, and the entire mass was thoroughly rubbed up and macerated with a pestle. This mass was then extracted with water, precipitated with alcohol, and otherwise prepared according to the method of J. W. Ellis, except that, because

of the relatively small amount of material, 100 cc. of water instead of 250 cc. was used for the initial extraction, and correspondingly smaller amounts of the various other ingredients during the course of the preparation.

(c) *Preparation of the Doubly Adrenalectomized Series.*—Animals were prepared for the injection of this toxin by double adrenalectomy, the adrenals being removed by the posterior or kidney route, great care being taken to remove both glands intact in every case. Prior to the injection of the toxin, adrenalectomized rabbits were allowed to survive for a period of two or three weeks, in order that they might fully recover from the effects of the operation and that any abnormalities following the injection of the toxin might reasonably be interpreted as due to it and not to any factor directly associated with the technic of the operation. No attempts were made to select rabbits with any particular care, either for the production of obstruction or in the case of the double adrenalectomy preparation.

Fig. 3.—Adrenal medulla in the dog following the production of ileus; low power photomicrograph, showing blood vessel dilatation and pseudo clot formation.

The rabbits were fairly large, weighing from 1 to 1.5 Kg. apiece. Some of them were angora, some were ordinary albino rabbits, while others were gray or yellow, many of them being piebald. During the course of the experiment no particular effort was made to control the diet of the animals; this consisted in all cases of bread and lettuce and as much water as the rabbit desired, together with grain in the form of oats.

Twenty-six rabbits were adrenalectomized during the course of the experiment, and of these only six survived the performance of the operation for a suitable length of time.

DOUBLE ADRENALECTOMY

Rabbit 1.—An albino female rabbit weighing 1.6 Kg. was operated on on Aug. 22, 1928. The operation was started at 2 p. m., and completed at 2:35 p. m. There was considerable hemorrhage. The animal reacted from the anesthetic, but died at 3:30 p. m. of hemorrhage.

RABBIT 2.—A piebald female rabbit weighing 1.5 Kg. was operated on on Aug. 22, 1928. The operation was started at 3:05 p. m. and completed at 3:50 p. m. There was considerable hemorrhage. The animal did not react from the anesthetic, and died at 3:55 p. m.

RABBIT 3.—An albino male rabbit weighing 1.1 Kg. was operated on on Aug. 22, 1928. The operation was started at 4:22 p. m. and completed at 4:40 p. m., and the rabbit was returned to his cage in apparently good condition. At 6:30 p. m., however, it was found dead. Autopsy showed the cause of death to be hemorrhage.

RABBIT 4.—A piebald male rabbit weighing 1.4 Kg. was operated on on Aug. 22, 1928. The operation was started at 4:55 p. m., and the animal was returned to his cage at 5:34 p. m. It reacted from the anesthetic, but died at 6:20 p. m. Autopsy failed to reveal the cause of death (insufficiency?).

RABBIT 5.—An albino female rabbit weighing 1.2 Kg. was operated on on Aug. 24, 1928. The operation was commenced at 2:13 p. m., completed at 2:52 p. m., and the animal was returned to its cage apparently in good condition. It reacted from the anesthetic, walked about the cage, and survived for the remainder of the afternoon, but was found dead the following morning. Autopsy failed to reveal the cause of death (insufficiency?).

RABBIT 6.—An albino female rabbit weighing 1.2 Kg. was operated on on Aug. 24, 1928. The operation was commenced at 4:22 p. m. The adrenals were fragmented during the course of the operation, and there was considerable hemorrhage. The operation was completed, and the animal was returned to its cage about 4:52 p. m. It was found dead at 5:28 p. m. Autopsy revealed the probable cause of death as hemorrhage.

RABBIT 7.—An albino female rabbit weighing 1.4 Kg. was operated on on Aug. 24, 1928. The operation was begun at 5:01 p. m. The adrenals were fragmented during the process of removal and considerable hemorrhage was encountered. The animal was returned to its cage at 5:38 p. m. apparently in a moribund condition; it survived only a few minutes. Autopsy revealed the probable cause of death as hemorrhage.

RABBIT 8.—An albino female rabbit weighing 1.4 Kg. was operated on on Sept. 17, 1928. The operation was begun at 2:52 p. m. The adrenals were both removed intact without hemorrhage. The operation was completed, and the rabbit was returned to its cage at 3:21 p. m. apparently in good condition. It survived throughout the afternoon, but was found dead the following morning. Autopsy failed to reveal the cause of death (insufficiency?).

RABBIT 10.—A piebald female rabbit weighing 1.1 Kg. was operated on on Sept. 17, 1928. The operation was commenced at 3:34 p. m. The adrenals were removed intact and without much hemorrhage. The rabbit was returned to its cage at 4:05 p. m. apparently in good condition. It survived the operation and was the first animal successfully doubly adrenalectomized and used in the series.

RABBIT 11.—An angora albino female rabbit weighing 1.6 Kg. was operated on on Sept. 17, 1928. The operation was commenced at 4:15 p. m. The adrenals were removed intact and without much hemorrhage. The operation was completed, and the animal was returned to its cage in apparently good condition at 4:58 p. m. It survived the afternoon, but was found dead the following morning. Autopsy failed to reveal the cause of death (insufficiency?).

RABBIT 12.—An angora albino female rabbit weighing 1.3 Kg. was operated on on Sept. 18, 1928. The operation was begun at 1 p. m. The adrenals were removed readily and with relatively little hemorrhage. The operation was com-

pleted, and the animal was removed to its cage at 1:28 p. m. It survived the afternoon and the following morning until 11:30 a. m., at which time death occurred. Autopsy revealed no apparent cause for death (insufficiency?).

RABBIT 13.—A white female rabbit weighing 1.3 Kg. was operated on on Sept. 18, 1928. The operation was begun at 1:11 p. m. The adrenals were removed intact with little hemorrhage. The operation was completed, and the animal was removed to its cage at 1:29 p. m. in apparently good condition. It survived and was the second animal used in the experimental series.

RABBIT 14.—A white female rabbit weighing 1.5 Kg. was operated on on Sept. 18, 1928. The operation was started at 1:55 p. m. The adrenals were removed with some difficulty; the left gland was fragmented during removal, and considerable hemorrhage was encountered. The operation was completed, and the

Fig. 4.—Normal adrenal medulla in the dog; high power photomicrograph.

rabbit was removed to its cage at 2:32 p. m. It survived the afternoon, but was found dead the following morning; autopsy showed the cause of death as hemorrhage.

RABBIT 15.—A brown female rabbit weighing 1.1 Kg. was operated on on Sept. 18, 1928. The operation was commenced at 2:50 p. m. Adrenalectomy was performed with little difficulty and with virtually no hemorrhage. The animal was returned to its cage at 3:12 p. m. in apparently good condition. Death occurred at 5:30 p. m.; at autopsy, no cause for death could be discovered (insufficiency?).

RABBIT 16.—A piebald female rabbit weighing 1 Kg. was operated on on Sept. 18, 1928. The operation was begun at 3:35 p. m. The adrenals were removed easily and with little hemorrhage. The animal was returned to its cage at 4 p. m. in apparently good condition. It survived the afternoon, but was found dead the following morning; autopsy failed to reveal the cause of death (insufficiency?).

RABBIT 17.—A piebald male rabbit weighing 1.4 Kg. was operated on on Sept. 19, 1928. The operation was begun at 1:28 p. m. Adrenalectomy was performed with facility and without much hemorrhage. The animal was returned to its cage. It survived and was the third animal used in the experimental series.

RABBIT 18.—A white angora male rabbit weighing 1.2 Kg. was operated on on Sept. 19, 1928. The operation was commenced at 2:11 p. m. The adrenals were removed with some difficulty, both being fragmented and considerable hemorrhage being encountered. The operation was completed and the animal removed to its cage at 2:41 p. m. in relatively poor condition. It died at 4 p. m.; autopsy revealed the probable cause of death as hemorrhage.

RABBIT 19.—A white female rabbit weighing 1.5 Kg. was operated on on Sept. 19, 1928. The operation was begun at 2:45 p. m. Adrenalectomy was unusually easy and relatively little hemorrhage was encountered. The operation was completed, and the animal was removed to its cage at 3 p. m. in excellent condition. It survived the night, but died at 10 a. m. the following morning. Autopsy failed to reveal the cause of death (insufficiency?).

RABBIT 20.—A piebald male rabbit weighing 1.3 Kg. was operated on on Sept. 19, 1928. The operation was begun at 3:05 p. m. The adrenals were removed intact without difficulty and without hemorrhage. The operation was completed, and the animal was removed to its cage at 3:20 p. m. It survived the operation and was the fourth animal used in the experimental series.

RABBIT 21.—A white female rabbit weighing 1 Kg. was operated on on Sept. 21, 1928. The operation was commenced at 2 p. m. The adrenals were removed with some difficulty but without much hemorrhage. The operation was completed at 2:35 p. m., and the animal was returned to its cage in fair condition. It died at 7 p. m.; autopsy revealed no apparent cause for death (insufficiency?).

RABBIT 22.—A white male rabbit weighing 1.5 Kg. was operated on on Sept. 21, 1928. The operation was begun at 2:51 p. m. The adrenals were removed intact with slight hemorrhage. The operation was completed, and the animal was removed to its cage at 3:15 p. m. in good condition. It survived and was the fifth animal used in the experimental series.

RABBIT 23.—A piebald female rabbit weighing 1.1 Kg. was operated on on Sept. 21, 1928. The operation was begun at 3:30 p. m. The adrenals were removed fairly easily but some hemorrhage resulted. The operation was completed at 3:50 p. m., and the animal was removed to its cage. It survived the afternoon, but was found dead the following morning; autopsy failed to reveal the cause of death (insufficiency?).

RABBIT 24.—A white angora female rabbit weighing 1 Kg. was operated on on Sept. 21, 1928. The operation was begun at 4:11 p. m. The adrenals were removed with some difficulty and slight hemorrhage. The operation was completed at 4:31 p. m., and the animal was removed to its cage in fair condition. It died at 5 p. m. apparently of shock; autopsy failed to reveal the cause of death.

RABBIT 25.—A white female rabbit weighing 1.2 Kg. was operated on on Sept. 21, 1928. The operation was begun at 4:45 p. m. Adrenalectomy was difficult and both glands fragmented; there was considerable hemorrhage. The operation was completed, and the animal was removed to its cage at 5:10 p. m. It survived the afternoon, but was found dead the following morning. Autopsy failed to reveal the cause of death (insufficiency?).

RABBIT 26.—A brown male rabbit weighing 1.4 Kg. was operated on on Sept. 25, 1928. The operation was commenced at 2:25 p. m. Adrenalectomy was

accomplished fairly easily, and not much hemorrhage was encountered. The operation was completed at 2:40 p. m., and the animal was removed to its cage. It survived and was the sixth animal used in the experimental series.

THE OBSTRUCTION AND INJECTION SERIES: THE EXPERIMENT PROPER

I. RABBIT 27.—A white female rabbit weighing 1.2 Kg. was used.

Obstruction was produced on Oct. 7, 1928, at 1:15 p. m. The animal was killed on Oct. 9, at 2 p. m., at which time it appeared ill. In the evening, the entire small intestine was removed and from the mucosa and the contents a toxin was prepared, according to the method of Ellis.

Fig. 5.—Adrenal medulla in the dog following the production of ileus; high power photomicrograph, showing pyknosis of nuclei and plasma cell infiltration.

RABBIT 33.—A brown female rabbit weighing 1.1 Kg. was used. The animal was healthy and normal.

RABBIT 10.—Adrenalectomy was performed on Sept. 17, 1928.

The toxin derived from rabbit 27 was divided into two equal parts (in this case 2.7 cc.); one part was injected into the normal rabbit 33, and the other into the adrenalectomized rabbit 10, at 3:15 p. m.

3:15 to 3:30 p. m.: Neither rabbit exhibited any particular symptoms except that both appeared disinclined to move about, and at the end of this period the healthy rabbit was found to have defecated several round, hard pellets.

3:30 to 4 p. m.: Both rabbits "drooped" considerably. The pupils of both were widely dilated, and the normal animal passed considerable quantities of fecal material which first was formed, though soft, but later became mucoid and watery; toward the last, tenesmus was prominent in this animal. The adrenalectomized animal did not defecate nor exhibit tenesmus; it appeared to have been much

less affected by the injection than the normal and was generally brighter and more attentive to its surroundings.

4 to 4:30 p. m.: During the early part of this period the normal animal looked as if it were about to succumb; it lay on its abdomen with legs stretched out before and behind, continued to purge at intervals, was quite apathetic to its surroundings, and was unable to stand or sit; tremors were noticed in the hind limbs but these did not persist. By the end of the period, however, it appeared much better and was beginning to pull up its legs in an attempt to get to its feet, although its efforts were unsuccessful. The adrenalectomized animal was able to sit up, but appeared sick. Both animals refused food, but toward the end of the period it appeared as if both would survive.

4:30 to 5 p. m.: There was little change in the appearance of either animal though both looked somewhat brighter and at the end of the period both were sitting up. It was decided to discontinue detailed observations at this time, and both were returned to their cages.

6 p. m.: The normal animal had apparently almost recovered; the adrenalectomized one was apathetic, but otherwise exhibited no particular symptoms.

7 p. m.: The normal animal had apparently fully recovered, though possibly was not as active as before the injection. The adrenalectomized animal was stretched out and dead.

The normal animal fully recovered.

Autopsy on the adrenalectomized animal revealed no gross lesions in any of the organs, with the single exception of the small intestine; here, in places, was some hyperemia, and the mucosa was reddened in patches. No adrenal tissue could be discovered after careful search.

II. RABBIT 28.—A piebald female rabbit weighing 1.4 Kg. was used. Obstruction was produced at 2 p. m., on Oct. 11, 1928, and the animal was returned to its cage in good condition. The animal was killed at 2 p. m. on October 13, and the contents and mucosa of the small intestine were used for the preparation of toxin according to the method of Ellis.

RABBIT 34.—A white female rabbit weighing 1.2 Kg. was used. The animal was healthy and normal.

RABBIT 13.—Adrenalectomy was performed on Sept. 18, 1928.

The toxin derived from rabbit 28 was divided into two equal parts (4 cc. each in this case); one part was injected into the normal animal and the other part into the adrenalectomized animal at 5 p. m., on Oct. 14, 1928.

5 to 5:15 p. m.: For the first five minutes neither rabbit appeared to experience any ill effect from the injection. However, at the end of this period the normal rabbit defecated a fairly large amount of normally formed stools, and also urinated. At 5:15, both animals were beginning to become somnolent; they sat huddled up with their eyes closed, and resisted any attempts to change their positions.

5:15 to 5:45 p. m.: During this period both rabbits progressively lost control of both hind legs, and the normal one was unable to bear his weight on his front paws. The normal rabbit purged violently; quantities of partially formed stools and, toward the last, very watery and mucoid motions were noted. The adrenalectomized animal passed a few formed fecal pellets. At 5:45 p. m., the normal rabbit was lying on his side with pupils widely dilated, apparently in a moribund condition. The adrenalectomized animal was in only a slightly better condition; it was able to struggle to maintain its position when disturbed, but could not roll onto his abdomen when turned on its side. Both animals presented slight tremors of the extremities.

5:45 to 6:45 p. m.: The adrenalectomized rabbit progressively became comatose, and died rather unexpectedly in convulsions at 6 p. m. The normal animal gradually regained the use of its limbs and was sitting up at 6:45 p. m.

The normal animal fully recovered.

Autopsy on the adrenalectomized animal revealed no gross lesions; examination of the region of the upper poles of the kidney revealed total absence of adrenal tissue.

III. RABBIT 29.—A white male rabbit weighing 1.5 Kg. was used. Obstruction was produced on Oct. 13 1928, at 3:15 p. m., and the animal was returned to its cage in good condition. The rabbit was killed at 4 p. m., on October 15, and toxin was prepared, as in previous cases.

Fig. 6.—Adrenal cortex in the dog following the production of ileus; low power photomicrograph, showing areas of focal necrosis.

RABBIT 35.—A white male rabbit weighing 1.2 Kg. was used. The animal was normal and healthy.

RABBIT 17.—Adrenalectomy was performed on Sept. 19, 1928.

The toxin prepared from rabbit 29 was divided into two equal parts; one part was injected into the normal animal and the other into the adrenalectomized one at 2 p. m. on Oct. 16, 1928.

No special features were noted in this case except that the reaction to the injection was somewhat delayed beyond the intervals previously noted in the case of both rabbits, and neither animal appeared very ill at any time during the first two hours. Both rabbits were returned to their cages at the end of this period with the idea that probably the toxin was relatively inert. In the morning, however, the normal animal was apparently healthy, while the adrenalectomized one was dead. Rigor mortis had become established in the latter animal.

The normal animal survived indefinitely.

Autopsy on the adrenalectomized animal showed no gross lesions of any of the organs. No evidence of adrenal tissue could be found.

IV. RABBIT 30.—A white female rabbit weighing 1.4 Kg. was used. Obstruction was produced on Oct. 14, 1928 at 1 p. m. On October 16, the rabbit was killed and toxin was prepared as in the previous cases.

RABBIT 36.—A brown female rabbit weighing 1.2 Kg. was used. The animal was normal and healthy.

RABBIT 20.—Adrenalectomy was performed on Sept. 19, 1928.

The toxin derived from rabbit 30 was divided into two equal parts (5 cc. in this case); one part was injected into the normal rabbit and the other into the adrenalectomized animal at 2:15 p. m. on Oct. 17, 1928.

The results in this case almost exactly duplicate those reported in the previous case. Both rabbits showed little effect from the injection of the toxin, and were returned to their cages at the end of two hours; the normal animal survived indefinitely, but the adrenalectomized one was found dead on the following morning. The autopsy observations were insignificant except in demonstrating that all adrenal tissue had been removed.

V. RABBIT 31.—A white angora male rabbit weighing 1.3 Kg. was used. Obstruction was produced on Oct. 16, 1928, at 1:30 p. m., and the animal was returned to its cage in good condition. The rabbit was killed on October 18, at 2:25 p. m., and the toxin was prepared as previously.

RABBIT 37.—A piebald male rabbit weighing 1.4 Kg. was used. The animal was healthy and normal.

RABBIT 22.—Adrenalectomy was performed on Sept. 21, 1928.

The toxin derived from rabbit 31 was divided into two equal parts (2.5 cc. in this case); one part was injected into the normal rabbit and the other into the adrenalectomized animal on Oct. 19, 1928, at 3:10 p. m.

3:20 p. m.: The normal rabbit defecated a quantity of soft formed stools; it appeared sick and its respirations and pulse rate were rapid. The adrenalectomized animal was unaffected.

3:30 p. m. The normal animal was weak and had some difficulty in maintaining its balance; the adrenalectomized animal began to look sick.

3:40 p. m.: The normal rabbit had purged violently mucous and watery stools. The adrenalectomized animal had also defecated, but the movements were normal.

4 p. m.: Both rabbits had become so weak that they could no longer stand. The pupils of both were widely dilated; the skins of both were deeply cyanosed. Both exhibited fibrillary twitchings in the rear limbs.

5 p. m.: Both rabbits were in essentially the same condition as previously, except that paralysis was more marked in the adrenalectomized animal.

6 p. m.: Both rabbits were very sick, but the formerly normal one had apparently recovered somewhat. Both were placed in their cages for the night.

8 p. m.: The adrenalectomized animal died in violent convulsions. The normal animal had recovered somewhat.

Two cubic centimeters of blood was taken from the ear veins of both animals for chloride determination just prior to the injection of the toxin and a similar amount at the end of two hours for the same purpose. The chloride determinations showed: in the normal animal prior to injection, 528 mg. per hundred cubic centimeters, while two hours after injection it was 518 mg. per hundred cubic centimeters; in the adrenalectomized animal prior to injection, 445.5 mg. per hundred cubic centimeters, while two hours after injection the amount was the same.

The normal animal survived indefinitely.

Autopsy of the adrenalectomized animal showed absence of all adrenal tissue. No significant organic changes were found, with the exception of moderate distention of the small intestine which was filled with liquid yellow contents and a great deal of mucus.

VI. RABBIT 32.—A white female rabbit weighing 1.5 Kg. was used. Obstruction was produced on Oct. 19, 1928, at 4:20 p. m., and the animal returned to its cage in good condition. The rabbit was killed on October 21, at 5 p. m., and the toxin was prepared as previously.

RABBIT 38.—A piebald female rabbit weighing 1.2 Kg. The animal was healthy and normal.

RABBIT 26.—Adrenalectomy was performed on Sept. 25, 1928.

Fig 7.—Adrenal cortex in the dog; high power photomicrograph of figure 6, showing pyknosis of nuclei and part of the area of focal necrosis.

The toxin derived from rabbit 32 was divided into two equal parts (3 cc. in this case); one part was injected into the normal (rabbit 38) the other into the adrenalectomized animal (rabbit 26) at 3:30 p. m. on Oct. 20, 1928.

No particular features of new interest were noted. Both rabbits experienced rather severe reactions within an hour; both became practically comatose in an hour and a half; they both exhibited some tenesmus, but the bowel movements of the normal rabbit were profuse and mucoid, while those of the adrenalectomized rabbit were scanty and formed, though soft and covered with mucus. Both animals were in apparently in extremis at the end of two hours. Two cubic centimeters of blood had been secured from the ear veins of both of the animals for a blood chloride determination just prior to the injection of the toxin. It had been decided to secure a similar amount at the end of two hours, in order that any possible decrease in chlorides might be detected. Both animals, however, were virtually

moribund at the end of two hours, as previously noted, and blood could not be secured from the veins of either animal. It was felt that neither animal could survive many minutes longer, and cardiac puncture was performed.

The adrenalectomized animal died during this procedure, possibly a cardiac death.

The normal animal recovered and survived indefinitely.

Autopsy on the adrenalectomized animal showed no adrenal tissue. The heart showed evidence of puncture, of course, but only a drop or two of blood was found in the pericardium.

The chloride determinations showed: in the normal rabbit before injection, 501.6 mg. per hundred cubic centimeters, and after injection, 495 mg. per hundred cubic centimeters; in the adrenalectomized rabbit before injection, 511.5 mg. per hundred cubic centimeters and after injection, 462 mg. per hundred cubic centimeters

SUMMARY

Under as similar conditions as could well be devised six pairs of rabbits were injected with toxin chemically prepared, in as pure form as possible, from the mucosa and intestinal contents of other rabbits in which obstruction had been present for about forty-eight hours. Each pair of animals that had been given injections of toxin consisted of one rabbit which was healthy and normal, as far as could be determined, and an animal from which both adrenals had been completely removed approximately two or three weeks previously, and which had apparently completely recovered from the effects of the operation. Precisely the same dose of toxin was injected into both animals of each pair, the toxin from one animal with obstruction being divided for the purpose into two equal parts. The weight of the normal animal of each pair was selected so as never to exceed the weight of the adrenalectomized one, thus throwing any possible advantage in favor of the operated animal.

The results were conclusive. Both animals of each pair showed the symptoms of intoxication that have been previously reported by several investigators: weakness, tremors, dilated pupils, diarrhea and tenesmus. The normal rabbits invariably showed much more severe reactions than the adrenalectomized rabbits, and diarrhea with tenesmus was a prominent feature of the intoxication. The adrenalectomized animals showed the latter manifestations in very mild degree. While the animals of the normal series all survived indefinitely, though after a period of alarmingly severe reactions in most cases, the adrenalectomized rabbits all died within a period of twelve hours, in spite of the apparently relative mildness of their reactions.

Blood chloride determinations in two pairs of animals showed either no decrease at all or only slight decrease in chloride content during the two hour period following the injection of the toxin, and while the animal showing the greatest decrease was one from the adrenalectomized series and, accordingly, died, the animal showing the next greatest decrease was a normal animal and lived. Furthermore, the other adrenalectomized

animal showed no decrease, though it died, while the other normal animal showed no significant decrease yet lived.

It is accordingly believed that these experiments demonstrate that:

1. The lethal dose of toxin derived from the mucosa and intestinal contents of animals in which obstruction has been produced is much less for doubly adrenalectomized animals than for normal ones.

2. The adrenal glands evidently serve a definite function in combating a toxemia produced by the injection of toxin so derived.

3. The severity of the symptoms and signs of such a toxemia are a false guide to the prognosis in cases in which the adrenals cannot function.

COMMENT

The present series of experiments will have little interest for those who feel that the characteristic toxin which can be prepared, as previously described, from the contents and mucosa of loops of intestine proximal to an obstruction is an adventitious substance that ordinarily does not find its way into the circulation and therefore has no essential part in the production of the toxemia of ileus. On the other hand, granted that the reverse is true, and that the toxin under discussion probably does enter into the etiology of the symptom complex, a new and most fascinating sidelight is thrown on the problem of intestinal obstruction by the apparent incrimination of the adrenal glands as agents in a protective mechanism against the toxemia. Unfortunately, in spite of the fact that the adrenal glands have been known for years to subserve such a protective mechanism in the case of other toxic substances, organic and inorganic, no effective way of reinforcing this protective action in times of stress and strain has as yet been devised either through the isolation of an efficient and injectable extract of the adrenal gland of other animals or by measures designed to support the gland of the affected animal during the period in which it is called on to carry a load which it cannot bear unaided.

All the evidence at present available seems to indicate that the cortex of the adrenal gland and not the medulla is the tissue responsible for the protective mechanism, but attempts to utilize this fact in a practical way have apparently thus far met with failure. Such cortical extracts as have been prepared have been disappointingly inefficient, although emulsions of cortical tissue have been shown to detoxify at least one biologic toxin (Cobra venom, Meyers²³), and autoplasmic transplantation of the adrenal cortex has been shown to increase the resistance of animals previously lowered by adrenalectomy (Jaffe²⁴).

24. Jaffe, H. L.: On Diminished Resistance Following Suprarenalectomy in the Rat and the Protection Afforded by Autoplasmic Transplants; Am. J. Path. 2:421, 1926.

On the basis of such fragmentary knowledge as is available at present, it seems probable that the influence of the adrenal cortex in combating intoxication is indirect rather than direct, and possibly a fairly complicated mechanism is involved. Perhaps the adrenals influence the general metabolism or the special metabolism of some intermediate tissue or they may control the usual mechanism of antibody production. In this connection the observation of Marine and Baumann is interesting—that the administration of physiologic solution of sodium chloride and Ringer's solution is of value in prolonging the life of those animals which ordinarily rather quickly succumb after double adrenalectomy, since the administration of sodium chloride is known to be of value in combating the toxemia of intestinal obstruction clinically.

From a clinical point of view it is believed that an appreciation of this protective function of the adrenal glands in intestinal obstruction is of the utmost importance. If, as seems to have been established histologically, these glands undergo degenerative changes in obstruction, it must be fairly obvious that treatment in order to be effective must be instituted early in intestinal obstruction, and such treatment must be aimed at the removal of toxic products from the obstructed loops of intestine before extensive degenerative changes have occurred in the adrenal cortices.

An amount of toxic absorption can be successfully combated by the body in the earlier stages when the adrenal mechanism is intact which would be rapidly and inevitably fatal once the cortical function has been seriously damaged.

Consequently, it would seem irrational to temporize very long with symptomatic treatment in any severe clinical case. The administration of spinal or splanchnic anesthesia in an attempt to relieve an adynamic ileus must be performed early and not as a last resort. In the early stages of obstruction the restoration of the motor function by any means will be effective, since the cortical protective mechanism is intact; later such restoration, though complete, may be just as hopelessly ineffective, since even though further absorption may be minimized or completely overcome, the protective mechanism may be unable to take care of the dose already absorbed.

In a similar way, enterostomy, to be effective, must be performed relatively early. It will almost inevitably allow the escape of only part of the toxic intestinal contents, and the condition of the cortical protective mechanism will determine whether the individual can successfully take care of the residuum or whether he will be overwhelmed thereby.

ACUTE COMPLETE OBSTRUCTION OF THE DUODENUM FOLLOWING A GASTROJEJUNOSTOMY

CURE BY DEGASTRO-ENTEROSTOMY *

JOHN E. SUMMERS, M.D.

OMAHA

The clinical fact has long been noted that the immediate seriousness of an acute intestinal obstruction depends on the location of the obstruction. When located in the duodenum, the higher the obstruction is below the opening through which the bile and pancreatic secretions are discharged, the more serious is the toxicity and the earlier the fatality. Numerous experimental occlusions of the duodenum have proved this.¹ Rapid fatalities follow obstructions in the small intestine, and the nearer the obstruction is located to the approach to the duodenum, the earlier death occurs. On the other hand, obstructions in the large bowel may exist for a considerable number of days before symptoms threatening life develop. Of course, if the obstructing cause, wherever located, so interferes with the vitality of the bowel that the blood supply is shut off, gangrene and peritonitis hasten the end. In such an instance, bacterial infection is overwhelmingly added to the causes of the commonly described toxemia. Not infrequently disorders of general health are noted in incomplete duodenal stenosis, most often located near the duodenojejunal junction.² However much one may agree or disagree with experimental physiologists³ that the chief danger in acute intestinal obstruction is the loss of water and the inorganic constituents of the blood, there is, in my opinion, no question that safety for the sufferer consists primarily in draining the intestine. This, when done early, is accomplished by relieving the obstruction itself. When the patient is not seen until late, only temporizing measures are permissible, and the procedure of a simple drain introduced into the bowel above the obstruction is indicated. It has been proved experimentally and clinically that sodium chloride, when administered, has a positive effect in reducing the toxicity in intestinal obstruction. It is given intravenously, subcutaneously and by rectum, in large quantities of water. The water is

corrective of the dehydration. If one should await the corrective effects of the toxicity resulting from the intravenous administration of sodium chloride before establishing drainage above the obstruction, I fear it would be bad judgment. The acts of intestinal drainage, intravenous administration of large quantities of physiologic solution of sodium chloride and blood transfusion should go hand in hand—at least that is my experience.

In papers of my own⁴ I have advocated the vital importance of draining the intestine above the obstruction, emptying the intestine through several incisions, when practicable. Forgetting for the moment chloride depletion, Holden⁵ has given the best corroborative evidence that the greatest danger of acute intestinal obstruction, wherever located, may be toxemia from absorption of the intestinal contents. Among his last fifty-one patients with acute intestinal obstruction on whom operations were performed, there were only three deaths, whereas, among a large number on whom operations were done before these his mortality rate was 50 per cent. He attributed his, probably to date unapproached, improved success to the fact that in each instance he practiced a method of emptying the imprisoned intestinal contents by a process of stripping, which caused almost complete emptying.

The foregoing digression from the subject of my clinical report seemed necessary because of the unusual opportunity afforded to discuss the dangers of delay, especially in high intestinal obstruction, as well as the possibilities of sustaining life by the measures advocated by physiologists.

REPORT OF A CASE

A well developed and well nourished man, aged 28, an intern, was admitted as a patient in the University Hospital on Aug. 28, 1927, with the diagnosis of acute appendicitis and duodenal ulcer.

History.—In 1917 had begun a spring and fall series of rather vague gastric discomforts which were relieved by sodium bicarbonate and the taking of food. These symptoms continued, but to a lesser degree, through the patient's premedical course. During the four years of the medical course there was again a feeling of distention and gnawing in the epigastrium about two or three hours after meals. It seemed to be aggravated by acid food and by periods of stress, mental and physical, but had practically no seasonal relationship. Fluoroscopic and roentgen examinations confirmed the clinical diagnosis of duodenal ulcer. The hospital record showed that the young man had the benefit of the modern recognized medical treatment for duodenal ulcer, and that in spite of carrying on his part of an active surgical service he led a relatively comfortable existence, provided he was careful of his diet.

5. Holden, W. B.: *Intestinal Obstruction: Survey of 135 Personal Cases*, *Arch. Surg.* 13:882 (Dec.) 1926.

The day previous to admission as a patient, he experienced colicky pain and cramps in the right lower quadrant, followed by nausea and vomiting. As there was no apparent urgency about the case—the only physical observations being some muscle spasm tenderness in the right lower quadrant—surgical intervention was delayed.

Operation.—On Sept 5, 1927, with the patient under general anesthesia, a high right rectal incision exposed the stomach and an area of induration near the

Fig 1—Gastrojejunostomy invaginated into stomach, obstructing adhesions had been removed

pylorus, 2 cm in diameter, on the anterior duodenal wall. A posterior gastro-enterostomy was considered advisable. The cecum was found to be undescended and was held high up under the liver. The appendix contained several hard concretions. The gallbladder appeared normal. An appendectomy was done and a routine posterior gastro-enterostomy performed. The patient was returned from the operating room in good condition. Seven hundred cubic centimeters of

physiologic solution of sodium chloride was given by hypodermoclysis, and 2,000 cc. by proctoclysis.

Progress.—Nothing abnormal was noted on the day of operation or on the second postoperative day. On the third day, there was a burning sensation in the epigastrium. The patient complained of considerable cramplike pain in the right lower quadrant, which was relieved somewhat by a colon tube and enema. On September 9, the administration of liquid diet was begun. The pain in the right

Fig 2—This and the following illustrations show steps in degastro-antrostomy. Invagination is reduced. The gastrojejunostomy is released by sectioning of the stomach, leaving a narrow cuff of the stomach attached to the jejunum.

lower quadrant continued, and the patient complained of thirst. Gastric lavage and enemas gave little relief. On September 10 and 11, nothing noteworthy was observed. On September 12, pain in the right side became severe and was followed by nausea and vomiting. By gastric lavage only a small amount of greenish

mucus was washed out. Thirst was becoming marked. The following day, pain and epigastric burning persisted; lavage was still being used, but little relief was obtained. Proctoclysis, 1,500 cc. of physiologic solution of sodium chloride was instituted. On the afternoon of the eighth day burning in the epigastrium and pain in the right lower quadrant became more severe and rhythmical hiccups developed, occurring from every five to ten seconds. Hoffman's anodyne, atropine, camphor, amyl nitrite and morphine were all tried without avail. Gastric lavage (5 per

Fig. 3—The upper part of the picture illustrates the suturing of the mucosa of the stomach; the lower part, the removal of the cuff of stomach from the jejunum

cent soda) gave no relief. After thirty-six hours of singultus, the patient fell asleep. An enema given later returned slightly colored, with a small amount of hard, formed feces. No flatus was passed. The cramps recurred. Proctoclysis, 500 cc. of 10 per cent dextrose, was given together with 700 cc. of physiologic solution of sodium chloride by hypodermoclysis. A Levine nasal tube was passed,

and magnesium sulphate injected through the tube produced no results. An enema returned slightly colored.

The patient was almost too weak to talk above a whisper. On the tenth postoperative day, 750 cc. of matched citrated blood was given intravenously, together with 250 cc. of physiologic solution of sodium chloride. On the eleventh day, there was considerable twitching. He talked incoherently. Fluids given by mouth were not retained, so that 1,250 cc. of physiologic solution of sodium chloride was given intravenously. On the twelfth day, the Levine tube was again passed, and 150 cc. of a greenish fluid was aspirated. An enema returned clear. Through the Levine tube, barium meal was injected into the stomach. Careful observation with the fluoroscope for from fifteen to twenty minutes failed to

Fig. 4.—The upper part of the picture illustrates the mucosa of the stomach sutured; suturing muscularis and peritoneum. The lower part shows the suturing of the mucosa of the jejunum.

show any of the barium leaving the stomach. Another 750 cc. of matched citrated blood was given in the afternoon of the twelfth day, and was followed by some heat and itching.

Second Operation.—At 4:30 p. m. on the afternoon of the twelfth day, a second operation was performed. The old incision easily separated and spread open with little evidence of repair. A mass of dense adhesions was found in the area of the operative field. There was a herniation of the jejunostomy anastomosis into the stomach which caused complete obstruction of the duodenum and a few inches of the jejunum below the ligament of Treitz, and closed the gastro-

jejunostomy opening by compression. All of the tissues were densely adherent. The hernia was released and the anastomosis uncoupled. The stomach and jejunum were rapidly closed with double rows of chromic catgut, and the abdomen was closed with through and through silkworm gut sutures. During the operation, the pulse rate had jumped to 164 and the blood pressure dropped to 88 systolic; the diastolic pressure could not be determined. My much interested colleagues and assistants were so exercised, thinking the patient would die on the table, that after the stomach was closed I was urged to put a tube in the jejunum and get the patient to bed. Fortunately, I did not follow this advice. During the operation, 200 cc. of physiologic solution of sodium chloride with

Fig 5—The upper part of the picture shows the burying of the suture line in the stomach by the Cushing right-angle continuous stitch; the lower part, the suturing of the muscularis and peritoneum of the jejunum.

10 minims (0.6 cc) of epinephrine was given intravenously. The patient was returned from the operating room in an extreme state of shock; the body was cold and clammy, and the lips were cyanotic. The pulse could not be felt. Respiration had ceased. The foot of the bed was elevated, and a suction machine was used to remove mucus from the pharynx. A towel clip was put through the tongue to hold it forward and to aid in artificial respiration. Epinephrine, 10 minims, was given intravenously. The entire body was rubbed vigorously. Physiologic solution of sodium chloride with 20 minims (1.25 cc.) of epinephrine was given slowly by hypodermoclysis. After thirty minutes of artificial respiration, the apex beat could be guessed at 165 with the stethoscope. The respirations were

very shallow, but became more regular and full. Oxygen was administered; proctoclysis, with physiologic solution of sodium chloride, was begun. The patient was restless throughout the night. Just before operation a subnormal temperature had jumped to 103 F., the pulse rate to 164 and the respirations to 35. On the second day following, the temperature had dropped to 99.6 F., the pulse rate to 100, and the respirations to 20.

Fig 6.—The stomach is fastened to the mesocolon by interrupted stitches. The wounds in the stomach and jejunum are closed.

Progress.—On September 19, 300 cc. of matched citrated blood was given intravenously, with 250 cc. of physiologic solution of sodium chloride about twenty-four hours after operation. Because of cramping and some nausea, gastric lavage with 2 per cent soda was given: this brought back some clear, dark-colored fluid. Abdominal pains were severe and were best controlled by heroin, which was the only narcotic to which the patient was reasonably susceptible. On September 20,

nausea persisted, but it was not so troublesome as before. There was a severe stomatitis, the result of dehydration. Air hunger was marked. One thousand two hundred cubic centimeters of physiologic solution of sodium chloride with 10 per cent dextrose was administered intravenously. On September 21, the cramps decreased, and the patient began to tolerate some fluids. Epigastric burning was relieved by sodium bicarbonate. On September 25, after ninety-six hours, some soft food was added to the liquids. On the eighth postoperative day, difficulty in swallowing was noted. There was pain underneath the sternum, radiating to the back. It was necessary to discontinue food and liquids for twenty-four hours and to limit the diet for the next three or four days in order to relax a probable cardiospasm. On October 10, the diet was gradually increased, and on the twelfth day the abdominal sutures were removed. Activities were renewed by degrees, and the patient was dismissed from the hospital in good condition on the nineteenth day following the second operation.

COMMENT

The delay in doing the second operation was due to two factors: 1. The patient objected to having anything done, being convinced that he was suffering from a dilated stomach. 2. There were too many physicians interested in the case, and no one was in command.

Since dismissal, or for the last one and a half years, the patient has remained on a soft, acid-free and roughage-free diet, and has not had many symptoms. The weight has returned to normal, and he has carried on his duties, feeling better than before the illness began. He is an active, hard-working man with a healthy appearance. X-ray pictures have demonstrated the stomach and duodenum functioning normally.

From the standpoint of animal experimentation, this man's life was saved from the intoxication of the duodenal block by the administration of large quantities of sodium chloride before and after the release of the obstruction. The symptoms exhibited in this case just before the second operation were not those commonly observed in cases of much lower intestinal obstruction when seen late. They resembled more those seen in infants with congenital pyloric stenosis—the neglected case. I once operated on one of these infants in the stage of convulsions—in fact, it had a convulsion while I was operating, and marvelously, the child lived.

Occasionally, it is necessary to release a gastrojejunostomy. I have employed a technic which when the urgency of the procedure admits is carried out as indicated in figures 1 to 6. Thalheimer⁶ employed a somewhat similar method. It is different in that the closures in the stomach and jejunum are made at right angles to the long axes of the stomach and jejunum; the method of suturing is also different.

PERICARDOTOMY FOR PYOPERICARDIUM *

L. G. BOWERS, M.D.

DAYTON, OHIO

When one considers the modern surgical optimism regarding the treatment for pyoperitoneum and pyothorax, the reluctance which has characterized surgical drainage of purulent exudate from the pericardial sac seems difficult to appreciate. In a masterly treatise on this subject, Winslow and Shipley¹ were able to collect only 118 recorded cases from the world's literature dealing with this subject.

Drainage of exudate contained in the pericardial sac was probably first suggested by Riolanus,² in 1648. It was not until 1855, however, that drainage of the pericardial sac through an opening in the sternum was first practiced by the Frenchman, Malle.³ Larrey,⁴ in 1829, first successfully employed the xiphocostal route. It remained for Hilsmann, in 1844, to cure a patient of pyopericardium by the performance of pericardotomy. Little attention was paid to the procedure until 1879, when the classic report of Rosenstein focused attention on the possibilities of the operation. More recently the successes of Winslow and Shipley and Peterson⁵ should serve to popularize this relatively simple procedure; in the opinion of the former writers, operative treatment should yield about 70 per cent of cures.

The purposes of this paper are to discuss briefly the etiologic factors responsible for the disease and its diagnostic characteristics, to describe a recent experience and to outline a simple operative procedure.

In all probability, suppurative pericarditis never primarily arises in the pericardium. In most instances it represents an extension of some infectious process of the lung and pleura. Lobar (pneumococcus) pneumonia invariably extends to the pleura, producing an inevitable fibrino-purulent pleuritis. In many instances, pyothorax results and may involve the pericardium by contiguity. In many cases, the disease has followed perforating knife or bullet wounds with direct implantation

of the infective agent. In other instances, the pyopericardium has been attributed to a local manifestation of a septicopyemia, such as that associated with osteomyelitis.

The failure to make a proper diagnosis of pyopericardium is so often revealed at the autopsy table that a brief recitation of the essential diagnostic criteria seems justified. The first requirement is the recognition of those diseases in which pyopericardium is a secondary manifestation.

FIG. 1.—Roentgenogram of chest showing greatly enlarged heart shadow and left pneumothorax.

If this is accompanied by a careful consideration of the history and physical examination, together with roentgenographic studies and diagnostic aspiration, the diagnosis should present no great difficulties. The most common physical signs are enlargement of the area of precordial dullness, frequently with shifting of the upper limit of dullness on changing the position, rapid pulse and respiration, muffled heart sounds, friction rub in the early stages and dull tympany over the infrascapular area. The difficulties encountered in distinguishing pyopericardium from car-

diac dilatation are indicated by the frequent performance of paracentesis cordis when paracentesis pericardii was being attempted. In simple dilatation the heart sounds are clear and sharp, whereas in pericardial effusions the sounds are distant and muffled.

REPORT OF CASE

B. L., a youth, aged 17, was first seen by Dr. P. A. Kemper, Germantown, Ohio, on April 12, 1928, when he complained of severe pain in the lower left side

FIG. 2.—Roentgenogram taken after aspiration of 925 cc. of turbid semipurulent fluid from pericardial sac, showing little decrease in size of heart shadow.

of the chest. He had a nonproductive cough, temperature of 102 F., pulse rate of 100 and increased respiratory rate. Physical examination revealed dulness over the lower half of the left side of the thorax. A diagnosis of lobar pneumonia was made. During the next five days, the symptoms and signs were aggravated. Ten days after the onset of illness, flatness was found on percussion, and drainage by the closed method yielded 1 liter of turbid straw-colored fluid during the first twelve hours. From April 22 until May 1, a moderate amount of exudate escaped, at the end of which time the patient experienced repeated chills and

sweats, dyspnea and cyanosis. On May 3, he complained of pain over the area of the liver. Dr. Kemper found considerable enlargement of the liver. At this time the heart sounds became more distant, the area of cardiac dulness became larger and the patient became orthopneic. The pain shifted to the interscapular region and increased as the area of cardiac dulness became larger.

On May 5, 1928, the patient was referred to me, with the diagnosis of left-sided lobar pneumonia, with empyema and purulent pericarditis. On admission to the Miami Valley Hospital, respirations were labored, even when he was in a sitting position; cyanosis was marked; the dulness around the liver extended

FIG. 3.—Drawing showing location of curvilinear incision along the left border of the sternum, beginning at the fifth left sternochondral junction and extending lateralward just below the inferior border of the sixth rib.

below the umbilicus; the superficial thoracic veins were greatly dilated; the heart sounds were distant and muffled; the area of cardiac dulness was greatly widened, and the legs were edematous. The temperature was 101 F., the pulse rate 120 and respirations 35. Fluoroscopic examination and stereoscopic films of the chest (fig. 1) showed a heart shadow which occupied fully three fourths of the thoracic cavity, together with left pneumothorax.

On May 7, 925 cc. of turbid, semipurulent fluid was aspirated from the pericardial sac. This gave the patient temporary relief from his respiratory embar-

FIG 4—Drawing showing method of introduction of gallbladder trochar into pericardial sac

FIG 5—Drawing showing position of catheter fixed with purse-string suture

rassment, but did not appreciably decrease the area of dulness around the heart (fig. 2). Pneumococci were recovered from the aspirated exudate. During the next twenty-four hours, the patient became obviously worse, and on May 9, pericardotomy was done under local anesthesia.

A curvilinear incision was made along the left border of the sternum, beginning at the fifth left sternochondral junction and extending lateralward just below the inferior border of the sixth rib to a point 2 cm. to the left of the costochondral junction (fig. 3). The flap was dissected upward from the underlying rib, exposing the costal cartilage of the sixth rib. The costal cartilage was removed.

FIG. 6.—Drawing showing point of exit of catheter through stabwound in fifth intercostal space 1 inch above incision. The catheter is connected with a tube leading to a drainage bottle.

The pleura and lung were drawn lateralward by means of a broad retractor with a short hook. An aspirating needle attached to a Luer syringe was then introduced into the pericardial sac to determine the depth and location of the exudate. This was followed by the introduction of a gallbladder trochar into the sac (fig. 4). Approximately 600 cc. of thick purulent fluid escaped by gravity through the trochar and attached tube. A large Luer syringe was then attached to the free end of the tube and about 200 cc. of purulent fluid were withdrawn by suction. A purse-string suture was placed around the trochar, after which it was with-

drawn from the sac and a male catheter of similar caliber introduced and fixed with the purse-string suture (fig. 5).

The pericardial sac was then irrigated with 1 liter of physiologic solution of sodium chloride, at the end of which time the fluid returned clear. During the irrigation many large flakes of fibrin were washed out. The catheter was then drawn through a stab wound 1 inch (2.5 cm.) above the incision, near the sternum, and the wound was closed with interrupted sutures. The drainage tube was then connected with a tube leading into a large bottle containing antiseptic fluid (fig. 6).

The patient experienced immediate relief from the dyspnea and cyanosis, and the dependent edema rapidly diminished. The liver decreased in size and the

FIG. 7.—Heart showing typical fibrinopurulent pericarditis ("cor villosum" or "shaggy heart").

cardiac shadow returned to approximately normal. The lumen of the catheter was kept open by daily injections of sterile saline solution.

During the four days following the operation, the patient showed marked improvement. On the fifth day, however, he showed signs of overwhelming sepsis, and he died on May 16, one week after operation.

Post-mortem examination revealed: left empyema (pneumococcus type); complete atelectasis and unresolved lobar pneumonia of the left lung; fibrinopurulent pericarditis ("cor villosum" or "shaggy heart") (fig. 7); organizing right-sided adhesive pleuritis; marked cloudy swelling, fatty degenerative infiltration and chronic passive congestion of liver, kidneys and myocardium; ascites of mild degree, and edema of the legs.

COMMENT

The immediate response to the simple operation was striking and gratifying. In view of the fact that the exudate which collects in the relatively small pericardial sac can find no physiologic outlet, it seems logical to contend that the early institution of surgical drainage offers to the patient his greatest hope. Two factors are in operation which constitute a serious handicap to the heart's work: first, the degenerative effects on the myocardium produced by the local inflammatory process; and second, the mechanical handicap produced by the rapidly increasing imprisoned exudate in the sac. Pericardotomy is a simple operation, presenting little or no risk, and is capable of saving life. The foregoing operative procedure is presented with the hope that it will stimulate others to give it a fair trial.

GANGLIONEUROMA OF MEDIASTINUM REQUIRING SURGICAL INTERVENTION FOR RELIEF OF OBSTRUCTIVE SYMPTOMS*

T. F. RIGGS, M.D.

AND

L. P. GOOD, M.D.

PIERRE, S. D.

Patients on whom it is possible to use only palliative surgical procedures are, unfortunately, often seen. Occasionally, the pathologic condition found gives rise to considerable discussion because of its relative infrequency.

Mediastinal tumors requiring surgical intervention because of symptoms of tracheal obstruction are rare. Of these, tumors arising from the sympathetic nervous system are perhaps the most rare. Because of its rarity and interest, we wish to report a case of ganglioneuroma apparently arising from the thoracic or the cervical segment of the sympathetic system.

REPORT OF A CASE

History.—A. B., a boy, aged 4 years, was admitted to St. Mary's Hospital on Nov. 20, 1925, with the complaint of difficulty in breathing and of swelling in the right side of the neck. The maternal grandfather was said to have died of cancer of the stomach and the paternal grandmother of cancer of the liver. A paternal uncle had died suddenly at the age of 6 months from an unknown cause. The boy was born on Oct. 22, 1921, delivery being normal. The mother did well and the child developed normally. No abnormality was noted in the other children in the family and there had been no serious diseases. The patient had had no headaches, pain in the chest, croup, gastro-intestinal disturbances or genito-urinary disease. Movements of the bowels were regular. He had a light attack of influenza in January, 1924, and contracted scarlet fever on March 1, the same year.

Three weeks after the onset of scarlet fever, or on March 22, a swelling was noted in the right anterior cervical triangle. The parents were assured that the condition was probably secondary to scarlet fever. The swelling persisted for nineteen months, but no symptoms developed until the latter part of October, 1925, when the patient had a severe cold, persistent cough, increasing hoarseness and pressure symptoms.

Examination.—The patient was a moderately nourished boy in considerable respiratory distress, as evidenced by cyanosis, stertor and voluntary respiratory efforts. There was a fulness in the right anterior triangle of the neck similar to that of a tuberculous adenitis. The left side of the neck was apparently normal. The right pupil was larger than the left, and the pupillary reflex was diminished. The tonsils were of the cryptic type, touching in the midline. On palpation of

* Submitted for publication, May 30, 1929.

* Read before the Western Surgical Association, Dec. 15, 1928.

the right side of the neck, there seemed to be two masses, each composed of lobules, rather firm, attached to the deep structures but not to the overlying skin. They were not tender. One mass extended from beneath the sternomastoid muscle toward the midline, while the other extended downward and was lost beneath the clavicle. Examination of the chest was unsatisfactory, owing to the respiratory noise.

Laboratory Observations.—On November 20, the urine was normal. The blood showed: red blood cells, 3,530,000; hemoglobin, 70 per cent (Dare); color index, 1; white blood cells, 5,500; polymorphonuclears, 65 per cent; small lymphocytes, 27 per cent, and transitionals, 8 per cent. The blood pressure was not taken. On Jan. 8, 1926, the blood showed: red blood cells, 2,500,000; hemoglobin, 52 per cent (Dare); white blood cells, 21,300; polymorphonuclears, 84 per cent; small lymphocytes, 9 per cent; transitionals, 5 per cent; polymorphonuclear eosinophils, 1 per cent, and polymorphonuclear basophils, 1 per cent.

Fig. 1.—Roentgenogram taken at the time of admission, showing a shadow in the right apex.

On Nov. 21, 1925, the roentgen report was: "There is a mass in the upper thorax which extends above the clavicle on the right side. The right border is well marked extending outward to the juncture of the middle and distal thirds of the clavicle and passing downward to the level of the fifth thoracic vertebra and rounding off toward the midline to be lost in the shadow of the spine. On the left, the border is not well marked, but the trachea is seen displaced somewhat to the left. This mass is smooth in outline and of uniform density. No changes of the bone are noted.

"Conclusion: This may be an abnormal thyroid; a thymus, or an 'hygroma.'"

Operation.—On the basis that the condition might possibly be an abnormal thymus, the patient was given four roentgen treatments, three over the upper thorax and one deep irradiation of the chest, but without appreciable benefit. On December 10, with the patient under an ether rausch, the tonsils and adenoids were removed in the hope that part of the respiratory obstruction might be relieved and as a preparatory step to a possible later operation on the neck. Section of the tissue

of the tonsil showed lymphoid hyperplasia and no other pathologic changes. On December 16, a second roentgen examination was made, concerning which the following report was made:

"Screen Examination: The cardiac shadow appears normal. There is a mass in the mediastinum extending down to the second interspace. It extends to the right displacing the right apex. Plate Examination: The cardiac shadow is normal; the bases are clear; there is an area of increased density involving the upper mediastinum from the level of the sixth dorsal vertebra upward. On the right it forms a curved line outward and upward obliterating the apex of the right lung and involving the neck above the clavicle. When compared with the previous x-ray there is no evidence of increase in size.

"Impression: Probable lymphosarcoma."

Fig. 2—Ganglion cells distributed throughout section, many showing nuclei and nucleoli. Homogeneous supporting tissue. Note the tendency to grouping of the cells. Hematoxylin and eosin; $\times 157$.

Course.—The patient was then temporarily discharged to recover from the tonsillectomy, and was readmitted on Jan. 6, 1926, at which time a roentgen examination showed a definite displacement of the trachea to the left at the level of the lower cervical and upper thoracic vertebrae. The patient's condition was pitiful—a typical picture of tracheal obstruction in an extreme form.

On January 9, an operation was done to relieve the tracheal obstruction, the various preoperative diagnoses recorded at that time being lymphosarcoma, lymphadenoma and thymoma. The gravity of the condition had been and was again fully explained to the parents, who were given to understand that we hoped for little more than temporary relief, and that a complete cure was out of the question.

A "T" shaped incision was made, one portion being parallel to the upper border of the clavicle and the other extending upward along the posterior margin of the sternomastoid muscle. A large mass of nodules was found deep in the neck,

intimately jointed with the right lobe of the thyroid and displacing the trachea to the left. This mass was removed and dissection carried downward underneath the clavicle, new growth being removed from about the common carotid artery and from above and beneath the subclavian vessels, and a mass of the growth was palpated in the mediastinum. It was impossible to determine the size or the extent of the growth. The incision was closed after a small roll rubber drain was placed at the lower point. Convalescence was rather slow and stormy but satisfactory in that the patient was completely relieved from dyspnea, which did not recur until a short time before death nearly eighteen months later.

On January 27, roentgen examination showed that the mass in the upper part of the right side of the chest was somewhat larger than on previous examinations. At the base of the right lung there was an area of increased density involving the lower third of the right lung field; this was more dense in the mesial half. There was a well marked, smooth, upper border suggesting either pneumonia, or a presence of fluid, but it may have been a metastatic growth.

The patient's temperature record showed marked variations. At the time of the first admission the temperature was normal and continued so, save for an occasional slight rise after roentgen therapy, until on December 4 when, without apparent cause, it began to rise, reaching 104 F. within twenty-four hours and dropping back to normal within forty-eight hours. Again after the tonsillectomy on December 10, there was a second similar febrile period, which subsided more slowly. At the time of the second admission, the temperature varied between 97.8 and 100.4 F. until after the operation on the neck, when it rose rapidly to 105 F. and was accompanied by a fine, general scarlatinal rash which was of not more than twenty-four hours' duration and was not followed by desquamation. The temperature, however, remained irregularly elevated for several days, subsiding gradually to normal for the first time on January 26, fifteen days after the operation.

After being discharged from the hospital, the patient was taken home, and letters from his parents reported him as playing actively and normally with his companions and being entirely relieved from his discomfort.

On May 16, 1926, he was again seen and appeared the picture of health. There was no palpable recurrence at the site of operation but percussion showed diminished resonance in the right apex. The report of the roentgen examination at that time was as follows:

"Plate examination of the chest shows a normal cardiac shadow. The diaphragm is normal in outline and the bases are clear. There is a definite shadow in the upper mediastinum which blends with the cardiac shadow. This increased density extends upward and to the right with a clearcut border and involves the right apex. There is also apparently an increased density in the neck on the right side. On the left the border of the heart blends with this mediastinal shadow which extends up to the level of the clavicle about 2 cm., to the left of the spine. When compared with the plate taken on Jan. 27, 1926, the shadow in the mediastinum shows no change. The increased density in the neck above the right clavicle is definitely less than it was at that time and the cloudiness at the right base has all disappeared.

"Conclusion: Tumor of the mediastinum."

The observations and the prognosis were again carefully explained to the parents, and permission, both verbal and written, was obtained for a necropsy when death occurred.

In June, 1926, the parents reported that they were putting the child in the care of a physician of another town who "treated by colored light." On April 2,

1927, the child was seen by Dr. Hagin and Dr. Gregory of Miller, S. D., who took a roentgenogram and confirmed our statement that the outlook was extremely grave, although stating that at that time the child's general condition was not acutely serious. They found a temperature of 100.4 F. and 13,000 leukocytes, and a blood smear showed some degeneration of the red corpuscles but no predominance of lymphocytes.

In May, 1927, the patient's condition began to decline, and on May 19 he was seen by Dr. C. E. Price of Orient, S. D. At that time the parents assured Dr. Price of permission for a necropsy. Shortly thereafter the patient developed a general edema, marked ascites and a recurrence of dyspnea. Death occurred at 6 p. m. on June 3, 1927. The parents absolutely refused a postmortem examination, which is greatly to be regretted, for study of the mass in the mediastinum and that in the area of the lung would have been most interesting and doubtless exceedingly instructive.

Pathologic Data.—Grossly, the material removed was of two kinds, one cellular and friable containing scattered yellowish pinpoint areas and the other grayish white, rather uniformly firm but elastic, each unit or nodule apparently having a thin covering or capsule. The former proved to be thyroid and the latter, neoplasm. On section, the tumor appeared to be made of a fine, closely interlacing structure which was grayish white and firm. A fibrous capsule was present and varied from 1 to 2 mm. in thickness.

The tumor was fixed in a diluted solution of formaldehyde, U. S. P. (1:10). It was embedded in paraffin from which sections were cut and stained with hematoxylin and eosin, van Gieson's stain, Orlandi's modification of Bielschowsky's silver method, thionin, Mallory's phosphotungstic acid and Weigert's myelin-sheath stains.

On microscopic examination, the tumor was fairly dense and consisted mainly of an interlacing fibrous framework supporting some nonmedullated nerve fibers. Ganglion cells were rather evenly distributed throughout the tumor mass. They usually occurred singly, though in places they were seen in groups (fig. 2). Most of these cells were mature, but they varied in size considerably. Some of them were multinucleated (fig. 3), each nucleus having a distinct nucleolus. In some of the cells, the nucleus appeared to be in a process of division while in others the nuclei were widely separated. The cytoplasm apparently was unaffected by the nuclear division. Nissl's granules were distributed throughout the cytoplasm (fig. 4), with a tendency to greater density about the periphery. Many of the cells were surrounded by a definite nucleated capsule. In sections stained by Orlandi's silver impregnation method, definite dendritic processes could be seen to come from the cells (figs. 5 and 6). These processes forked at varying distances from the cell. Many of the cells had undergone cystic degenerative changes (fig. 3).

In no section examined were there "rosetts" or undifferentiated cells suggesting neuroblasts which are occasionally associated with ganglioneuromas.

ORIGIN OF GANGLIONEUROMA

Perhaps the outstanding paper in English on the subject of neuroblastoma and ganglioneuroma is that by Wahl,¹ who gave a concise but thorough review of the literature to 1914. We have drawn freely

¹ Wahl, H. R.: Neuroblastoma. With a Study of a Case Illustrating the Three Types that Arise from the Sympathetic System, *J. M. Research* 30:205, 1914.

Fig. 3.—Multinucleated ganglion cells with Nissl's granules. Note the characteristic nuclei and nucleoli. Tendency for cystic degeneration of these cells (a). Thionin; $\times 450$.

Fig. 4.—Ganglion cell with single nucleus and a distinct nucleolus. Note the Nissl granules. Thionin; $\times 1,000$.

Fig 5—Ganglion cell with multiple dendrites, one of which divides some distance from the cell. Orlandi, $\times 450$

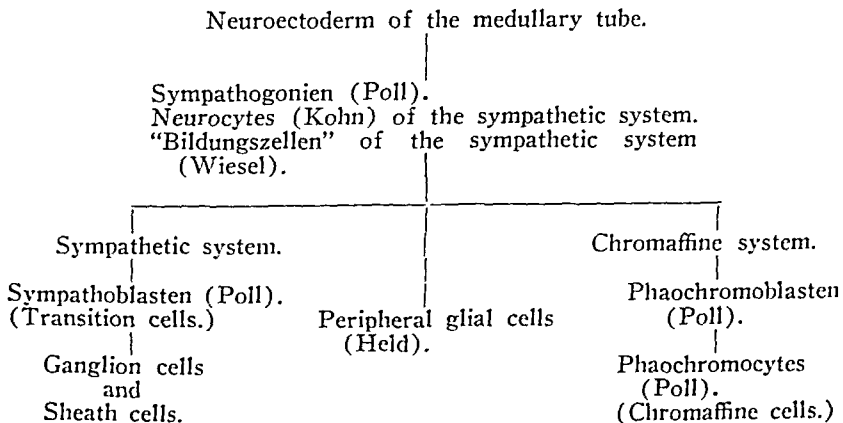

Fig 6—Ganglion cell showing a dendritic process which divides shortly after leaving the cell Orlandi; $\times 450$.

on this paper for information in making a study of our case. He pointed out, in the light of Kohn's work on the development of the sympathetic system, that "The embryonic sympathetic cells are not migrating pre-formed ganglion cells but are simple neurocytes formed in situ that have, locally, a different power of differentiation from elsewhere, in that they become differentiated on the one hand to ganglion cells, capsule cells, nerve fibers, and sheath cells and even glial cells, and on the other hand, to the chromaffine cells."

Simply stated, tumors of the sympathetic system arise from a cell rest, a mother cell called the neurocyte which has multipotential characteristics. The type or types of cells which characterize a tumor arising from the sympathetic nervous system depend, therefore, on the degree of differentiation to which the cells composing it have progressed.

CLASSIFICATION

Tumors arising from the sympathetic nervous system are divided into three main groups: (1) the neuroblastoma, (2) the ganglioneuroma and (3) the paraganglioma. The neuroblastoma is composed of undifferentiated cells and is malignant. These cells resemble lymphoid cells and are frequently arranged in rosets. The ganglioneuroma and paraganglioma are composed of highly differentiated cells and are benign. The former consists chiefly of ganglion cells, while the latter consists of cells having great affinity for the chrome salts similar to those of the medulla of the suprarenal gland. Between the undifferentiated cells of the neuroblastoma and the fully differentiated cells of the ganglioneuroma and paraganglioma there are cells in various stages of transition known as transitional cells. The genetic relation of the different nerve elements of which such tumors are composed is clearly expressed in the following scheme taken from Wahl.¹

This genetic relationship makes it easy to understand the varied histologic picture which is frequently encountered in a single tumor.

Two or more nerve elements frequently have been observed in a single case, and in the case presented by Wahl all three types of tumor were present.

A girl, aged $2\frac{1}{2}$ years, was markedly anemic and had had abdominal symptoms for several months, with irregular temperature, abdominal distention and enlargement of the inguinal lymph nodes. On examination, an irregular firm and fixed mass was found in the umbilical region. The postmortem observations as they pertain to this case were: malignant neuroblastoma of the sympathetic system arising in the left suprarenal gland and celiac plexus with metastasis to the liver, lymph glands, kidneys and left suprarenal gland; ganglioneuroma and paraganglioma of the left suprarenal gland.

To indicate the occurrence of two or more types of cells in a tumor, Robertson,² in 1915, suggested a fourth group. In this group, he placed tumors of group 1 in combination with either group 2 or 3, or both. For example, the tumor in Wahl's case would be designated ganglioparaganglioneuroblastoma and would be placed in group 4.

In the same year, Dunn³ reviewed the literature on the subject and grouped the tumors according to the region from which they had arisen. He collected fifty-one cases, the tumors of which had taken their origin in the following regions: four in the cervical segment, five in the thoracic segment, nineteen in the abdominal segment, eleven in the suprarenal gland, two in the subcutaneous tissue, four in the central nervous system and six in the peripheral nerves.

Reports of about sixty-five cases of ganglioneuroma are now recorded in the literature. Of this number, there are six cases which apparently have arisen intrathoracically; there are three cases, including ours, which have involved both the neck and the thorax and there are three cases which have been reported as arising in the neck (tables 1 and 2).

Loretz⁴ is credited with having given the first description of ganglioneuroma and, incidentally, of one of the cases of intrathoracic ganglioneuromas:

A woman, aged 35, was found unconscious and in convulsions. She died the same day, and at autopsy, a smooth subpleural tumor, 7.5 by 4.5 by 4.5 cm., was found in the left thoracic cavity in the region of the second and third thoracic vertebrae. Grossly it was composed of two layers. The outer layer was light and consisted of fibrous tissue, blood vessels and fatty tissue. The central layer was more grayish and softer, resembling a section of the uterus. It consisted mainly of nonmyelinated nerve fibers in which there were rather typical ganglion cells.

The case reported by Martius⁵ closely resembles the one reported by us and is worthy of being recorded here:

A boy, aged 2½ years, had a tumor in the right side of the neck which displaced and compressed the trachea. He was operated on because of dyspnea. At operation, the tumor was found intimately associated with the right lobe of

the thyroid from which it was thought to arise. The patient died a short time later. At autopsy, two masses of tumor were found. One was nodular and extended from the right side of the thymus downward and medially to the right atrium, and surrounded the superior vena cava and main bronchus. This tumor mass contained undifferentiated and partly differentiated cells and was malignant. To the side and below, and somewhat separated from this mass, was a tumor

⁵ Martius, K.: Maligner Sympathoblastentumor des Halssympathikus teilweise ausdifferenziert zu gutartigem Ganglioneurom, Frankfurt. Ztschr. f. Path. 12: 442, 1913.

occupying the angle formed by the first and second ribs with the spine. It was 3.5 by 2 by 0.75 cm., smooth and firm and resembled a myoma. The tumor was composed of well differentiated ganglion cells and nonmedullated nerve fibers. It was considered benign. It was thought that the two masses of tumor had a common origin in the sympathetic nervous system, and that they differed only in degree of differentiation. As the sympathetic system from the midcervical to the first thoracic was intimately involved in the tumor, it was considered to have arisen in this region.

In 1924, Brunner⁶ reported a case:

A girl, aged 19, for a period of two months previous to coming under his care, had had oppressive pain in the back and left side when lying down. Because of the pain, she could lie down only half an hour at a time. She obtained immediate relief on sitting up. Various diagnoses had been made, the final one being intra-thoracic dermoid cyst. On examination, the patient was found to be of medium size. From the upper border of the scapula down to about the tenth dorsal vertebra there was almost complete dullness, and over which the breath sounds were diminished.

Roentgen and fluoroscopic examination showed a nonpulsile shadow, the size of a child's head, extending from the second to the ninth dorsal vertebra on the left. It was in close relationship to the spine. The anterior mediastinum was clear.

The patient was operated on by Sauerbruch. A paravertebral incision was made, and several ribs were resected over the mass. Exploration revealed a smooth, firm, round tumor slightly adherent to the pleura and markedly adherent around the aorta. The tumor arose from the posterior mediastinum, pushing the lung ahead of it. No attempt was made to remove the tumor at this stage. The cut edges of the pleura, however, were stitched to the tumor mass. At a later date, a second stage operation was done, at which time the tumor was removed with great difficulty. The patient had a stormy convalescence, developing a sterile empyema and finally a necrosis of the left lung which sloughed away entirely. This was thought to have been due to tying of the bronchial artery at the time of the operation. Several operations were done to relieve the symptoms arising from the complications. Incidentally, the patient developed club fingers, but the author pointed out that this was due not to the tumor but to the complications in the lungs.

The gross specimen measured 17 by 12 by 8 cm. and was lobulated. The surface of the cut section had a silky sheen and was grayish white. The tumor had a definite capsule, and connective tissue septums could be seen.

Microscopically, the tumor was composed of nerve fibers, the nonmedullated variety predominating, in which there were collections of rather normal-appearing ganglion cells. Some of them, however, had undergone cystic degeneration. The whole was supported by a structure of wide-meshed connective tissue.

Ganglioneuromas arising in the cervical segment have been removed surgically in two cases, those reported by Glinski⁷ and Freund.⁸

6. Brunner, A.: Die erfolgreiche operative Entfernung eines grossen Ganglioneuroms des hintern Mittelfellraumes, *Arch. f. klin. Chir.* **129**:364, 1924.

7. Glinski, S. K.: Ganglioneurom, *abstr., Deutsche med. Wchnschr.* **32**:2044, 1906.

8. Freund, P.: Ein Ganglioneurom des rechten Hals-sympathikus, *Frankfurt. Ztschr. i. Path.* **13**:266, 1913.

Freund's case was that of a boy about 6 years of age who had had a tumor in the right side of the neck for a year. He developed dyspnea three days before admission to the hospital. Operations in both instances were apparently successful.

SUMMARY

A case of ganglioneuroma arising from the thoracic or the cervical segments of the sympathetic system is reported.

The patient was a boy 4 years of age. The duration of the tumor was twenty-two months; that of the acute symptoms, three months. Operation was performed for relief of the tracheal obstruction; the complete removal of the growth was not possible. Complete relief was obtained for sixteen months. Death followed one month after the recurrence of symptoms.

Pathologically, the tumor showed typical ganglion cells in a bed of nonmedullated nerve fibers, some ganglion cells showing cystic degeneration.

VARIATIONS IN THE EXTRAHEPATIC BILIARY TRACT *

MEREDITH G. BEAVER, M.D.
Fellow in Surgery, The Mayo Foundation
ROCHESTER, MINN.

The frequent recourse to surgery for disturbances in the function of the extrahepatic biliary tract makes imperative exact knowledge not only of the normal distribution of the bile ducts but of the variations occasionally encountered in this system.

The literature contains frequent references to this fact, and many cases are reported of injuries to the biliary tract during operation on subjects in whom the arrangement of the bile ducts was atypical. Jacobson¹ reported a case in which he severed the common bile duct during an operation for gallstones, because the cystic duct paralleled the hepatic duct for some distance. Many instances of similar accidents have been reported. Werelius² and Ginsburg and Speese³ reported cases in which transection of the common duct had been caused entirely by an anomalous arrangement of the ducts. Stetten⁴ reported a case in which the hepatic duct was divided instead of the cystic duct because of the parallel arrangement of the two.

Ruge⁵ described the various forms of the biliary tract and classified them under three main types. The first type consisted solely of the normal angular mode of union of the cystic duct with the hepatic duct. The second type of anomaly included those in which the cystic duct paralleled, for a certain distance, the choledochus. The third type included the two arrangements of the cystic duct in which, instead of leading directly into the right side of the hepatic duct, it wound around it, either anteriorly or posteriorly. Eisendrath⁶ (1918 and 1920)

presented a study of 100 cases in which the variations in the biliary tract and their relations to the vascular system were discussed. He described each type of variation and specifically stated its significance in relation to accidents during operation. Flint⁷ described two cases, noted clinically, of variations in the distribution of the biliary tract. In one, an accessory cystic duct was encountered during operation for gallstones; in the other, in which operation for cholecystitis was carried out, the cystic duct paralleled the choledochus for its entire length and emptied directly and independently into the duodenum. In an embryologic and comparative study of aberrant biliary vesicles in man and other mammals, Boyden⁸ presented valuable data concerning the frequency with which duplication of the gallbladder may be encountered. In studies on 10,000 domestic animals and reports on 19,000 cadavers and patients in hospitals, the incidence varies somewhat as follows: once in 8 cats; once in 28 calves; once in 85 sheep; once in 198 pigs, and once in from 3,000 to 4,000 human beings. Accordingly, such duplication of the biliary vesicle appears to be relatively rare in man.

A variation from the usual distribution of the biliary ducts, however, is common. Therefore, since cholecystectomy is now more common than simple drainage of the gallbladder, a clear understanding of the more common variations in the distribution of the bile ducts is imperative.

DATA OBTAINED DURING DISSECTION OF CADAVERS

In this report, I wish to present the data which were accumulated during careful dissections of fifty-seven cadavers. The material for these dissections was obtained from necropsies performed for the coroner in Portland, Oregon, and the study was made in the laboratories of the Department of Pathology, the University of Oregon Medical School.

The extrahepatic tracts of the fifty-seven subjects which came under my observation in this study fall into four rather distinct groups. I was able to demonstrate the three types of distribution as described by Ruge and in general to confirm his observations as to the frequency of these variations. The first group of cases, those in which the angular mode of union maintains between the cystic and hepatic ducts constituted 58 per cent of all the dissections (fig. 1 a).

I have subdivided Ruge's second group of variations, those in which the cystic duct coursed parallel to the common bile duct, by arbitrarily

7. Flint, E. R.: Gallstones Associated with Anomaly or Injury of Bile Ducts, *Brit. M. J.* **1**:995, 1924.

classifying the cystic ducts into two groups on the basis of their length. Furthermore, although the two ducts concerned are bound together in a fibrous union, their lumens are separate. Therefore, it seems better to speak of the cystic duct as running parallel to the hepatic duct and not to the common duct. I have designated the cystic ducts which

Fig. 1.—Mode of union of cystic and hepatic ducts: *a*, normal angular; *b*, long parallel; *c*, short parallel, and *d*, anterior spiral.

follow the hepatic bile duct as far as the upper border of the duodenum, as the short parallel type (fig. 1 *c*), and I have designated the ducts which extend farther, to within 1 cm. of the ampulla of Vater, as the long parallel type (fig. 1 *b*). In both of these types, however, the cystic and the hepatic ducts are bound together so intimately by fibrous connective tissue that it is almost impossible to separate them. In this

series, 26.3 per cent of the ducts were of the short parallel type and 7 per cent were of the long parallel type. The delayed juncture of the cystic and hepatic ducts, as in these variations, results in a greatly lengthened cystic duct and a relatively short common bile duct. In these aberrant cystic ducts, however, the valves were restricted to the

Fig. 2.—a, posterior, spiral mode of union of cystic and hepatic ducts; b, accessory right hepatic duct; c, accessory left hepatic duct, and d, accessory right hepatic duct emptying into the cystic duct.

normal site, for the remaining portion parallel to the hepatic duct was invariably patent throughout.

Of all the cases that came under my observation, 12.3 per cent could be placed in Ruge's third group, the group which includes the anterior and the posterior cystic ducts. In these variations the cystic

duct passes either anteriorly or posteriorly around the hepatic duct, describing from a quarter to a full turn around it. In my series, 7 per cent of the cases were of this anterior spiral variation (fig. 1 *d*) and 5.3 per cent were of the posterior spiral type (fig. 2 *a*).

To these three main types of anomalies, I have added a fourth, which includes variations in the distribution of accessory ducts. The first of these is an accessory hepatic duct which courses from the liver at the extreme right of the portal fissure and empties into the extra-hepatic biliary tract anywhere between the point of confluence of the right and left hepatic ducts and the orifice of the cystic duct (fig. 2 *b*). This particular type of accessory hepatic duct has been hitherto described, but these accessory ducts have been found in the right side of the liver only. In my series a second accessory variation was occasionally encountered (fig. 2 *c*). This duct leaves the liver at the left of the portal fissure and empties into the left hepatic duct before the latter joins the right hepatic duct to form the main hepatic bile duct. As far as I have been able to determine, this left accessory hepatic duct has never been described before. Accessory hepatic ducts, both right and left, were encountered in 3.5 per cent of all subjects examined.

Furthermore, an additional type of accessory duct was encountered in 5.3 per cent of all cases. This duct leaves the liver on the right side of the portal fissure and enters into the cystic duct, instead of into the hepatic duct, just above the confluence of the cystic duct with the hepatic duct (fig. 2 *d*).

SUMMARY AND CONCLUSIONS

1. The normal angular mode of juncture of the cystic duct with the hepatic duct, as described in textbooks of anatomy, occurred in only a little more than half of the cases (58 per cent).

2. The long and short parallel types of cystic duct occur in more than a third of the cases and, as is shown by the literature, is perhaps the most common cause of accidents in biliary surgery. In such cases, there is a marked increase in the length of the cystic duct and a corresponding decrease in that of the common bile duct. The cystic duct and the hepatic duct are so intimately bound together by fibrous tissue that they are absolutely inseparable and thus appear as a single duct; any rough manipulation may tear the thin septum which exists between them. The large portion of a cystic duct of this type which remains following cholecystectomy may dilate and form a new gallbladder, probably with recurrence of symptoms. The cystic duct does not contain valves of Heister in the portion which lies parallel to the hepatic duct. The short parallel type occurred in 26.3 per cent of the cases in this series and the long parallel type in 7 per cent.

3. The anterior and posterior spiral varieties comprised 12 per cent of this series. The length in the anterior spiral variety conforms closely to the normal; in the posterior spiral variety the cystic duct is markedly lengthened, and the hepatic and common ducts remain about normal. It has been recorded that strong traction on the gallbladder is much more likely to tear off a spiral cystic duct than a duct with a normal arrangement.

4. Accessory hepatic ducts occurred in five cases, or 8.7 per cent of this series. Four of these were accessory right hepatic ducts, three of which were also accessory to the cystic duct. In one case there was an accessory left hepatic duct. The length and diameter of the accessory ducts corresponded closely to the normal cystic duct.

KIDNEY

Surgical Technic.—Deming¹ reported a study to determine the freedom of incisions about the pelvis and the relative significance of the adjacent vessels which might be cut or ligated accidentally or purposely. He observed that following elongation of the pyelotomy incision straight on to the kidney and to the lower pole the renal circulation is not impaired if the retropelvic vessels are conserved. Angulated incisions cause definite shrinkage of the kidney. The incision of choice is the elongated incision to the lower pole near the median line. The suture of the wound in the kidney should not include any of the larger vessels. Ligation of the retropelvic vessels causes considerable renal injury which is not easily repaired in a few months' time.

Tumors.—Martin² stated that tumors of the kidney fall into three groups, the chief of which consists of growths arising in the renal epithelium. Tumors of connective tissue origin are represented by sarcoma, and the third group is that of the mixed tumor.

Epithelial tumors may originate from three types of epithelium. From the epithelium of the renal tubules, adenomas and carcinomas arise. Papillomas and papillary tumors spring from the epithelium lining the pelvis and calices. The hypernephroma, or third type, arises from suprarenal rests included in the kidney during development.

* Submitted for publication, May 10, 1929.

2. Martin, E. K.: Tumors of the Kidney, *Brit. J. Surg.* **16**, suppl. no. 13:297, 1928.

Small adenomas not infrequently occur in the cortex of sclerotic kidneys. A single adenoma may arise in an otherwise normal kidney and grow so as to form a clinically recognizable tumor. Adenoma of the kidney, although originally benign, may become malignant.

Carcinoma of the substance of the kidney is more common in men than in women and is not especially associated with the presence of calculus. Grossly, the tumor may appear as a solid, white, infiltrating growth, which destroys and replaces the kidney without appreciably altering either its size or shape. Microscopically, this tumor is frequently a tubular adenocarcinoma, which reproduces the appearance of renal tubules.

The most common form of malignant disease of the kidney is a lobulated and encapsulated adenoma which is yellow or orange and which is often broken up by areas of necrosis and hemorrhage, as well as by the fibrous intersections between its lobules. Microscopically, a hypernephroma is composed of columns of large polyhedral cells, separated from one another by delicate connective tissue carrying thin-walled capillaries. The cells have a clear protoplasm containing fat. Parts of the tumor frequently show a compressed papillary arrangement of the cells in the columns. An exact line of demarcation between the hypernephroma and the papillary carcinoma has not been drawn.

Mixed tumors present a characteristic picture. They occur within the first three years of life, grow rapidly to a large size, and are uniformly fatal. In the early stage they are solid, opaque white, and clearly separated from the substance of the kidney. As they increase in size they may become cystic, and areas of necrosis and hemorrhage may develop. The microscopic structure is that of spindle cells in which are embedded imperfect tubules of columnar epithelium. Tracts of smooth or striated muscle are common, and other mesoblastic tissues, such as cartilage and elastic tissue, are sometimes represented.

Papilloma is a simple tumor with a marked tendency to recur and to take on malignant characteristics. Obstruction of the ureter by these tumors may cause hydronephrosis. Microscopically and grossly, the papillary character of the growth is confined to the surface. In the deeper part of the malignant tumors which infiltrate the kidney, the carcinoma is diffuse.

Sarcoma rarely occurs in the kidney in adult life.

A case of cystic adenoma of the kidney is reported. A large part of the kidney was occupied by an almost spherical tumor, which was composed of brownish material and which had been broken up by hemorrhage and necrosis. The growth was confined within a fibrous capsule and microscopically was an adenoma.

In a second case of adenoma of the kidney, the gross structure markedly resembled a polycystic kidney. The upper half of the kidney

was apparently normal. The renal capsule enclosed the growth, which was sharply demarcated from the substance of the kidney. The tumor was composed of cysts of various sizes, the largest being about 6 cm. in diameter, and the smallest almost microscopic in size.

Another interesting case is that of a papillary carcinoma occurring in one of the calices in a hydronephrotic kidney. The pelvis and calices were distended, and the renal tissue was greatly reduced. The growth occupied one of the lower calices, had infiltrated the surrounding substance of the kidney, and was visible on the surface of the organ. Microscopic examination disclosed squamous cell carcinoma.

Deming³ reported a case of sarcoma of the kidney in a boy, aged 29 days. Nephrectomy was performed under local anesthesia. The tumor was so large that approach was made through an incision in the right rectus muscle extending from the costal margin to the pelvis. The muscles were separated and the peritoneum was opened, exposing the tumor which extended from the liver above, being overlapped by it, to the pelvis below and to the umbilicus mesially. It was adherent above to the liver and the gallbladder, mesially to the ascending colon, and at its lower pole to the cecum and appendix. The adhesions were carefully freed, and the tumor was mobilized. But, as it was otherwise impossible to demonstrate the pedicle, the cyst was tapped, and about 100 cc. of blood and gelatinous fluid was aspirated. The pedicle was then clamped and ligated. The wound was closed in layers, with a small rubber tissue drain inserted at the lower angle. The patient withstood the procedure well, manifesting shock only when the pedicle was being held tense. He recovered readily from the operation and was well six and a half years later. Pathologic diagnosis was congenital spindle cell sarcoma of the kidney.

[COMPILER'S NOTE: The rarity of complete cure of sarcoma of the kidney in a young child makes this case of interest. The majority of cases of tumors of the kidney occurs in the first two years of life. Rarely is one seen and the patient operated on at such an early stage as that reported by Deming. Tumors are generally confined by the renal capsule. They may occur in any part of the kidney and generally involve the entire organ. Metastasis is uncommon and when it does occur is generally in the late stages. If metastasis or local extension has occurred, operation is often followed by a rapidly fatal outcome. Nephrectomy in most cases prolongs life and offers the patient the only chance of improvement. Earlier writers agree on the high mortality. Newer methods of surgical approach, improved asepsis, and at times avoidance of the peritoneal cavity have in most instances greatly

3. Deming, C. L.: Sarcoma of Kidney; Cured, *New England J. Med.* 199: 273, 1928.

reduced the older mortality figures, but definite cures, such as the one cited here, are few.]

Beer⁴ found it necessary to perform nephrectomy in 18 per cent of 271 cases of stone in the kidney in which renal tissue was destroyed. Pyelotomy, with or without nephrotomy, was the procedure of choice in the remainder of the cases. In 29 of the last 38 cases, he performed pyelolithotomy and in 1, wide nephrolithotomy. The increased use of pyelolithotomy was due to the fact that it saves the parenchyma of the kidney and assures complete removal of all calculous material. It may also be used in cases of complicated stones.

If the kidney cannot be delivered and it is necessary to perform nephrotomy, Beer performed a bloodless operation by placing a rubber tourniquet around the pedicle. In all cases he followed the principles of constricting the ureter to prevent fragments from falling into it and of having the roentgenograms of the kidney developed immediately after removal of the stones. In about fifteen cases of stones of complicated shape, fragments were still present but were easily located and removed.

Randall⁵ stated that there are three prevailing theories regarding the etiology of formation of stone. The first is the action of specific bacteria. The second is based on colloidal chemistry, beginning with the facts that calculi result from an abnormal type of crystalline precipitation, that normal urine holds water-insoluble crystalloids in solution because of the presence of protective colloids, that hydrogen ion concentration affects this solution, and that the colloidal matter in solution modifies the morphology of crystalline precipitates. Basing his experiment on these factors, Keyser produced calculi by disturbing the urinary colloidal balance. He concluded that this disturbance may be due to quantitative changes in the colloids normally present, or to the entrance of abnormal colloids into the urine, either from the blood stream or as products of local renal disease. The frequency of formation of stones in animals having a diet deficient in vitamin A is the basis for the third theory. Such calculi consist essentially of the characteristic insoluble phosphates of calcium and magnesium, and treatment by dietary measures has resulted in the successful disappearance of these stones.

In from 3 to 81 per cent of the cases, the nucleus of stones was composed of urates and uric acid. Oxalates were present in ratios from 5 to 66 per cent.

Randall expressed the belief that vesical calculi are uniformly secondary formations to foreign bodies, to vesical obstructions causing

4. Beer, Edwin: *Bemerkungen über die Technik der operativen Entfernung von Nierensteinen*, *Ztschr. f. urol. Chir.* **24**:601, 1928.

5. Randall, Alexander: *Rapidity of Growth of Urinary Calculi*, *Atlantic M. J.* **31**:937, 1928.

residual urine, to vesical diverticula, to renal lesions and to descending stones. Incomplete prostatic operation which prevents complete emptying of the bladder often predisposes to secondary formation of stones. It is recognized that phosphatic stones grow more rapidly than others and that their growth is markedly influenced by the presence of a foreign body or alkaline cystitis.

Randall reported the growth of a stone in one of his patients who had taken some pills containing methylene blue (methylthionine chloride, U. S. P.) for urinary trouble. At operation three years later, two calculi measuring 3 by 2.5 by 1.5 cm. were removed. On section, each appeared to be formed of pure ammonium urate; the laminae in the early growths were stained green, showing a growth of 2 cm. in the three year interval. In another of Randall's cases three stones were removed from the bladder, the largest measuring 4 by 3 by 2 cm. The growth, in eighteen months, was due to alkaline cystitis and a contracted vesical orifice. In a museum is displayed a string of four calculi, the largest measuring 3 by 3 by 2 cm., all adherent to a linen thread, which probably had been misapplied during herniotomy five months before.

Nay⁶ stated that renal stones should be considered recurrent only when proved not to have been overlooked. He expressed the belief that infection is the cause of calculi in a large number of cases. Preoperative treatment should consist of removal of the focal infection, if possible, and treatment of the kidney. Postoperative treatment is important because it helps to reduce the recurrence of stones by leaving the patient with a good uninfected kidney.

Herbst, in discussing the recurrence of stone in the kidney, considered that focal infections play only a small part in the cause and recurrence of lithiasis. It is his belief that renal retention and infection are the important factors in the production and reappearance of renal calculi, and that the correction of these conditions following removal will reduce the number of recurrences.

Mattes⁷ stated that urolithiasis is considered of rare occurrence in the colored race. In 1913, Pfister reviewed the literature and noted particularly the occurrence of renal stone in the colored people of Africa, South America and the German colonies. He observed that the appearance of calculi depends on the locality, the soil and the water, and that in some regions it is almost unknown. Pfister stated the belief that if the examination of the two races was equally thorough, stone would be found as frequently in the colored as in the white race. Mattes' figures show that there was three colored persons with stone to seven white in 1924, and in 1925 he noted a ratio of one colored to five white persons.

7. Mattes, A.: Renal Calculi in the Colored, *South. M. J.* 20:941, 1927; abstr., *Ztschr. f. urol. Chir.* 24:408, 1928.

Walthers stated that formation of stone in the negro was rare and that he had seen few cases. During a period of ten to twelve years in a hospital for the colored, Righton never observed stones although many roentgen examinations were made. Hayes did not observe a single case in three years. Many other urologists, among them Kelly, who sees a great many negro patients, report similar experiences.

Ray⁸ stated that urinary calculi commonly consist of certain substances insoluble in water and urine. Crystals of these substances are sometimes found in normal urine, but they are generally isolated and single. These particles may be held in solution, may deposit a fine sediment, or may form calculi, and are brought about by colloidal substance. Ray believed that the absence of colloids in the urine is brought about by certain pathologic conditions within the kidney, due either to local disease or to outside influences reacting on the organ.

Billington⁹ attempted to assess the value of the results of nephropexy. He considered it from two aspects: (1) the surgical success of the operation permanently replacing the kidneys in their normal position without unsatisfactory sequelae, such as pain in the loin or back, hernia of the wound and persistent sinus, and (2) its therapeutic value in curing or ameliorating the symptoms for which it is performed. At first the results were not satisfactory. In a large percentage of cases the operation failed to cure the abnormal mobility of the kidneys, and they were found loose again as soon as active life was resumed. Many operations fixed the kidney to the muscles of the back at too low a level, with the result that pain in the back was common and at times hydronephrosis developed. The use of silk and other nonabsorbable suture materials was followed by persistent sinuses, and extensive injury to the muscles of the loin led to a feeling of weakness and hernia. A further and common cause of failure is the incomplete character of the operation. One kidney only is replaced, while the other one, which may also be mobile, and a possibly diseased appendix are left untreated. Only when the surgeon is satisfied that both kidneys are in a normal position and that associated or secondary abdominal lesions may have been excluded or treated can success be claimed.

Billington has performed nephropexy on 1,500 patients, and it has been his object to replace both kidneys, if necessary, and to make sure that intra-abdominal lesions were not left undetected and untreated. The surgical results were satisfactory; in not a single instance has he found a kidney loose again. Of 163 patients who were traced, 71 (43.6 per cent) reported that the operation was successful, 41 (25 per cent)

9. Billington, William: *The Therapeutic Value of Nephropexy*, *Brit. M. J.* **2**:975, 1928.

reported that it was partially successful, usually indicating relief of renal symptoms but not all associated symptoms, and 51 (31.4 per cent) reported failure.

Pylonephritis.—LeComte¹⁰ discussed the anatomic changes brought about by pregnancy and their influence on renal drainage. It is a well-established principle of urinary lesions that any obstruction will sooner or later cause infection; its duration will depend on the degree of obstruction, and the extent of injury will depend on the length of time it is permitted to act. A second principle is that the hazard to the integrity of the kidney is in proportion to the distance that the obstruction occurs from it. Frequent painful urination and pyuria should be considered as indications of a possible serious infection of the kidney.

During pregnancy, the form of the urinary organs is changed and function is disturbed by the enlarging uterus. The urethra is elongated early and the bladder is soon compressed and drawn upward, so that by the third month it becomes an abdominal organ. Functionally, these changes lead to frequency and residual urine, with the common sequence of bacteriuria and inflammation. Sluggish peristalsis was noted in 80 of 100 normal pregnant women on whom cystoscopy was performed. The abdominal ureter and renal pelvis are commonly found dilated during pregnancy. Varying degrees of dilatation were noted in all normal pregnant and parturient women who were submitted to pyelography; all presented symptoms of renal pain, or infection was present. While changes are taking place in the lower tract, the ureters and renal pelves are being slowly dilated by the intermittent obstruction afforded by the enlarged uterus. In some cases, due to the patient's high resistance or the absence of bacteria specific for the tissues at hand, the process stops; in others, inflammation results. Occasionally a vicious circle is established, the bladder becoming infected and the kidneys becoming reinfected from the bladder, this infection occurring either from the blood stream or ascending along the lymphatics of the ureter. If these changes occur early in pregnancy and are not relieved by treatment, the fetus usually dies from the infectious toxemia and the uterus empties spontaneously.

LeComte stated the belief that the greatest aid in the recovery of an infected kidney is the establishment of free drainage. During pregnancy, this may be brought about independent of whatever treatment is given and may lead to a good result. In the way of treatment, rest in bed during the febrile intervals is indicated, and the patient should lie on the side opposite that infected as much as possible, in order to relieve the pressure of the uterus on the ureter by gravity.

10. LeComte, R. M.: *Kidney Infections During Pregnancy*, Virginia M. Monthly 55:481, 1928.

Duncan and Seng¹¹ reported a survey of the protective mechanism of the urinary tract of healthy pregnant and puerperal women. They observed that physiologic forces external to the ureter cause obstruction to ureteral and renal drainage in pregnancy, which is relieved almost immediately on termination of gestation. Right-sided ureteral dilatation is constantly present; hydronephrosis on the right occurs only slightly less frequently. The left ureter and renal pelvis escape this dilatation in a high percentage of cases. Bilateral hydro-ureter and hydronephrosis were of common occurrence, and were apparent earlier, more frequently and in more marked degree in the multipara than in the primipara.

Stasis, as measured by inability of the renal pelvis and ureters to empty themselves within the normal time limits, is definitely and almost universally observed in women before delivery. It is still persistent in a less degree over a prolonged period after delivery.

Duncan and Seng demonstrated an unexpected amount of pus and coliform organisms in specimens from the bladder and kidney of supposedly healthy pregnant women and in women after delivery. They concluded that every pregnant woman has some degree of obstruction, definite dilatation of the ureters and renal pelvises, and well defined stasis continuing over a long period. They further demonstrated that in the apparently healthy pregnant and puerperal patients there is a probable renal complication, the presence of pus and coliform organisms. The line of demarcation between the physiologic and pathologic conditions in these cases is fine. These authors expressed the belief that these women are all subjects for potential pyelitis.

Blanton¹² stated that pyelitis is the most common urologic disturbance found during early life. It may arise as a primary infection but usually follows some other acute infection, such as tonsillitis, bronchitis or pneumonia. As a primary disease it is usually present during the early months of life, and mainly in girls, as a result of the proximity of the urethral opening and the anus and also of the short urethra in the female. It is caused chiefly by the colon bacillus and tends to be an ascending infection, the bacilli traveling up through the urethra and bladder to the pelvis of the kidney by way of the ureter or lymphatics. It may also be due to direct extension of infection from some nearby organ, such as the appendix or other portion of the intestinal tract. When it results from a hematogenous infection, the causative organisms are carried from some distant focus to the renal pelvis, where inflammation occurs. Any obstruction to the urinary flow from the kidney

11. Duncan, J. W., and Seng, M. I.: Factors Predisposing to Pyelitis in Pregnancy, *Am. J. Obst. & Gynec.* **16**:557, 1928.

12. Blanton, J. L.: Pyelitis of Infancy and Childhood, *Virginia M. Monthly* **55**:479, 1928.

predisposes to infection. The common causative organisms, in their order of frequency, are the colon bacillus, *Staphylococcus albus* and *Staphylococcus aureus*, the streptococcus, the typhoid bacillus, the pneumococcus and *Bacillus pyocyaneus*.

The acute form of pyelitis is characterized by sudden onset, frequently with a chill, followed by high fever and sweating. Chronic pyelitis may follow the acute form, or it may arise as a complication of some other disease and pass unrecognized unless discovered by urinalysis. It may exist for months or even years without causing typical symptoms.

Alkalis or antiseptics may be used in the treatment for acute pyelitis. The alkaline treatment is indicated in those cases in which the urine is acid, small in quantity and full of pus cells. Some alkaline diuretic, such as potassium citrate or acetate, or a combination of alkaline diuretics, should be used and fluids forced. If the pyuria is not cleared up promptly by this method, Blanton uses the antiseptic treatment, which tends to make the urine sterile. The common antiseptic used is hexamethylenamine or methenamine. He considers the cystoscope an aid in the treatment of many patients, even young children. The attempt should be made to eliminate all obstruction to the urinary flow and to treat the condition locally by means of lavage with antiseptic solutions; this is often successful when medical treatment fails.

Tuberculosis.—Greifenstein and Kehl¹³ reported forty-three nephrectomies for renal tuberculosis performed at the surgical clinic of the University of Marburg between 1891 and 1923. A follow-up study was possible in forty-one cases. The period of operative mortality extended from one to six months. In a second danger period of from one to three years, deaths caused by tuberculous complication occurred. Thirteen patients died. This high mortality was due to the primitive diagnoses and treatment of the earlier period. Histologic studies frequently disclosed bilateral renal tuberculosis when clinical proof was lacking. The mode of infection of the second kidney was the same as that of the first, namely, hematogenous. Infection by the urinary route can occur only in cases of advanced tuberculosis of the bladder.

The follow-up study of cases in which nephrectomy was done revealed that the patients remained tuberculous and succumbed sooner or later to tuberculosis. The prognosis appears more favorable in women. In men, genital tuberculosis does not exert any greater influence on the prognosis than that of any other organ, provided it is not complicated by active pulmonary tuberculosis. Of thirteen patients

13. Greifenstein, A., and Kehl, H.: Die Ergebnisse der Behandlung der Nierentuberkulose in der chirurgischen Klinik zu Marburg, Deutsche Ztschr. f. Chir. 208:1, 1928.

living, eight were entirely cured, four were improved, and one was worse. Injury to the peritoneum during nephrectomy on the right side rarely resulted in peritonitis. On the other hand, infection of the wound and the formation of fistula occurred in 17 per cent of the cases. The method of treating the stump of the ureter did not seem to be of any significance in this connection. The fistulas healed, as a rule. Nonsurgical treatment of renal tuberculosis is not to be considered, although in rare cases cure is possible through complete destruction of the organ in the absence of all symptoms.

Scholefield¹⁴ reported seventy-four cases of renal tuberculosis with fifty-nine nephrectomies from the Peter Bent Brigham Hospital. Two patients died within the first few weeks after the operation, and six died after a few years. Eighteen of the patients traced are known to be alive and well more than three years after the operation, while only eight are known to have continued symptoms of urinary tuberculosis. The remaining twenty-five were observed recently, or were lost track of before the end of three years.

Of the fifty-seven patients leaving the hospital, twenty-three (40 per cent) reported primary healing of the lesions, which remained healed. In twenty-four cases (42 per cent) sinuses developed which required attention for from three months to several years.

Scholefield concluded that in cases in which, at operation, the kidneys appeared little diseased sinuses were more apt to occur than in those in which extensive caseation was present. Involvement of the ureter or of the perinephric fat did not seem to have any bearing on the healing of the wound. The average period during which symptoms had been present was twenty-eight and six-tenths months in cases in which lesions healed, and sixteen and three-tenths months in those in which sinuses developed. The more acute the process, therefore, the more likelihood there is for the development of a sinus. Scholefield suggested that these sinuses are due not to the continuation of any existing infection but to the development of a new tuberculous process in the traumatized tissues of a patient whose resistance is lowered.

Cathelin¹⁵ stated that the dictum of Albarran that early nephrectomy is essential in renal tuberculosis still holds good. He discussed several complications following the removal of tuberculous kidneys.

Lumbar fistula is a commonly observed sequel after renal tuberculosis. Twenty or thirty years ago, fistulas were common, but today, with the present methods of surgical technic, they are fewer. So-called

14. Scholefield, B. G.: *Renal Tuberculosis: Healing of Tuberculous Nephrectomy Wounds*, J. Urol. **20**:345, 1928.

15. Cathelin, F.: *Les séquelles de néphrectomie pour tuberculose rénale*, Rev. gén. de clin. et de thérap. **42**:321, 1928.

urétéraux forcés, or dilated ureteral orifices, with urinary reflux, are rare at the present time.

Cathelin reviewed the histories in forty-five cases of nephrectomy. In most of them the lesions healed in from five to ten months, and in the majority of the remainder, in from ten to sixteen months after operation. In three of the cases the condition lasted for from eighteen to twenty-two months; in one for twenty-four months, and in another for thirty-one months. Cathelin follows two primary rules: he never washes the wound, and touches the base of the wound as little as possible. Reopening of the wound occurred in fifty of Cathelin's cases.

Occasionally there is considerable pain in the remaining kidney, due usually to hypersecretion and hyperfunction. This painful phenomenon is usually explained by simple reflex excitations and intermittent congestion.

Continuation of the symptoms in the bladder occurs in about 50 per cent of the cases. In half of these there is no change following operation, and in the other half there is moderate amelioration. In the remaining 50 per cent of the cases, the condition clears up completely. Cathelin uses oil of gomenol, 10 per cent strength, injecting 5 cc. every second day. On alternate days bladder lavage is carried out.

Fronstein¹⁶ stated that 80 per cent of patients with renal tuberculosis who are treated by conservative methods die in the course of five years after the onset of the disease. After ten years, practically none is living. On the other hand, about 75 per cent of patients operated on live their normal span of life. The postoperative results vary directly with the length of time the symptoms have been present preoperatively. The earlier the diagnosis and operation, the more satisfactory the results. One of the significant diagnostic points is the finding of bacilli of tuberculosis in the urine. Albuminuria is also of significance. Fedoroff observed albuminuria in 85 per cent of his cases. In Fronstein's series, it occurred in all cases. Dysuria is an early symptom and occurs in 94 per cent of the cases. Pyelography is of exceptional value in diagnosis.

Fain¹⁷ stated that while the bacillus of tuberculosis causes specific changes, it may at the same time bring about nonspecific nephritis, nephrosis and cirrhotic changes. In such a tuberculous kidney, tubercle formation is frequently not to be discovered. The course of a non-specific renal change may be slow and end with contraction. With non-specific tuberculous nephritis there may also be specific changes, and for that reason the diagnosis may be undetermined in each case. The pathologic-anatomic mutations show the frequency of bilateral tuber-

16. Fronstein, R.: Le diagnostic de la tuberculose rénale, *J. d'urol.* **25**:434, 1928.

17. Fain, L.: Ueber die Frühdiagnose und Therapie der Initial formen der Tuberkulose der Harnorgane, *Ztschr. f. urol. Chir.* **24**:421, 1928.

culous nephritis. Clinically, the differential diagnosis of tuberculous nephritis and tuberculous bacilluria is quite difficult and sometimes impossible, especially if there is a history of a common disease of the kidney. The difficulty in diagnosis is due to the similarity of the clinical manifestations of these diseases, which necessitate long observation and repeated examinations of the patient. In nonspecific renal changes associated with a tuberculous bacilluria or tuberculous nephritis, the absence of pyuria or the presence of slight or easily treated pyuria of the pelvis is characteristic; at the same time, the cystitis is of the non-ulcerative type and treatment is carried out in the usual manner, with relief. The additional renal pyuria which does not yield to the customary treatment, associated with severe cystitis and diminution in renal function, shows in most cases a destructive renal tuberculous infection. In the event of operative treatment for nonspecific infections of the kidneys which permit the passage of bacilli of tuberculosis, or in kidneys showing tuberculous nephritis, it is advisable to use some conservative procedures, such as decapsulation, nephrotomy, pyelotomy or ureterotomy. Such patients must remain under constant observation, since the kidney operated on conservatively is in continual danger of undergoing tuberculous changes and necrosis.

Cystic Disease.—Crosbie¹⁸ stated that large solitary cysts of the kidney should not be confused with smaller cysts occurring in nephritis and in sclerotic kidneys. Large cysts are usually unilateral and never connect with the renal pelvis, and the remaining renal tissue is as a rule normal. The cyst is usually situated at one pole of the kidney. It is more common in woman than in man, and the fluid is clear, straw-colored and rarely bloody. Symptoms are referable to the pressure of the cyst either on the remaining part of the kidney or on other organs. Hematuria is rare.

Treatment is operative. If the cyst is situated at one pole, it may be possible to do a resection and save the remainder of the kidney. Crosbie reported the case of a large cyst in the median portion of the kidney, in which nephrectomy was performed. On section the cyst was found to be lined by smooth, shiny, glistening tissue. There was an incomplete septum which partially lobulated the cyst. The fluid content was pale and clear, and there was no evidence of infection.

Barney, in discussing Crosbie's paper, reported a case of renal cyst in which the main symptoms were hematuria and retention of urine. At operation the kidney seemed to be in good condition elsewhere, so he trimmed off the cyst at its juncture with the cortex. In an effort to

18. Crosbie, A. H.: Solitary Cyst of the Kidney, *New England J. Med.* **199**: 277, 1928.

dissect out the lining membrane of the cyst from the cortex, he encountered considerable bleeding, so instead the cavity was swabbed out with Zenker's fluid.

Blood Supply.—Ferrer¹⁹ stated that distention of the renal pelvis and calices to their normal capacity will produce distinct, partial obstruction to the outflow of venous blood in the kidney, which is proportionate to the degree of distention. Any obstruction to the free outflow from the renal pelvis will tend to produce renal passive congestion, and a continuously distended pelvis may aid in the formation of hydronephrosis.

Ferrer expressed the belief that pyelovenous backflow is only a temporary phenomenon, and will persist only as long as the venous outflow fails to increase in pressure sufficiently to overpower that of the backflow. A more complete understanding of this type of obstruction will lead to better use of a permanent catheter, or at least of ureteral drainage and dilatation in many of the obstructive uropathic conditions encountered, especially in pregnancy. Pyelography should be done with care, and there should be a tendency to rely more on small amounts of concentrated solution than on weak but larger amounts of fluid.

Renal Reflexes.—Papin²⁰ stated that the nerve tracts of the kidney and its pelves carry two types of fibers, sensory and vasomotor, and that there are two types of reflexes, plain and secretory. Only the normal kidney is the seat of pain sensations. One of Papin's cases is illustrative of this. There was severe pain in the left loin due to right-sided hydronephrosis. Following removal of this lesion, the pain in the left kidney disappeared. Up to the present, observations show that the reflex pain in the normal kidney more often is associated with nephrolithiasis and less frequently with movable kidney, hydronephrosis, pyelitis, tuberculosis and renal tumors.

In the involvement of the kidney, and especially of the renal pelvis, the pain is not precipitated in the organ itself, but is referred to the corresponding Head's area on the surface of the body, usually on the same side; occasionally it is referred to both sides and in rare cases to the opposite side.

The problem of reflex secretory disturbances is still far from being clearly understood. Its manifestations are oliguria and, in rare cases, polyuria. Clinical observation has shown the following types: fatal anuria in unilateral obstruction; oliguria in a unilateral lesion, which

19. Ferrer, J. C.: Obstruction to the Venous Circulation in the Kidney Caused by Distention of the Pelvis and Calices, with Special Reference to Pyelovenous Backflow, *J. Urol.* **20**:701, 1928.

20. Papin, E.: Actions réflexes réno-rénales, *Arch. d. mal. d. reins* **2**:518, 1927; abstr., *Ztschr. f. urol. Chir.* **24**:335, 1928.

may be aided by removal of the diseased kidney; transient anuria following nephrectomy or a conservative renal operation, and polyuria after nephrectomy. One form of reflex polyuria occurs in tuberculosis, explained by Graser as a reflex of the pathologic conditions of the kidney brought about by vesical pollakiuria. Papin observed true reflex polyuria of the normal kidney in a case in which nephrectomy was done for hydronephrosis associated with infection. Clamps were left in place because of a short pedicle; polyuria developed, the amount of urine reaching 6,000 cc. by the fifth day. Following removal after the clamps were removed, the output diminished to 2,000 cc., where it remained.

Experimentation has not furnished any definite facts. The production of reflex anuria has been successful only in rare cases in which the condition was not clearly defined. The question as to whether anuria can occur in a normal kidney, whether the anuria may be permanent, or whether it disappears with the removal of the cause has not been solved. According to Neuwirth, reflex anuria is brought about through a spastic condition of the intrarenal vessels, which come through the vasomotor paths. This reflex is abolished by a break in the vasomotors (splanchnic anesthesia). Further researches of Neuwirth, and later of Koennekes, have shown that the splanchnic nerves carry not only vasomotor but sensory fibers, afferent and efferent, which can be affected by the same factors.

The question of reflex polyuria is even more doubtful. Experimentally, the only fact proved is that there is a polyuria center in the tuber cinereum of the medulla. Polyuria caused by splanchnic section is only transient, and always involves the same side.

Papin noted that clinical experience has yielded a few facts to explain some of these secretory disturbances. Nephrectomy has usually been difficult, and either the clamps were left on the pedicle or the ligatures had to be applied close to the large vessels. This probably caused direct irritation or destruction of the ganglions in these coursing reflex tracts.

Wounds.—Harris²¹ reported a case of rupture of the kidney which he diagnosed by means of pyelography more than three weeks after the injury. He was impressed by the tremendous recuperative and reparative power of the kidney. He stated the belief that these patients are generally not observed long enough to determine that mechanical defects have not, at a later date, been followed by complicating infection and even by the formation of stone, resulting ultimately in destruction of renal tissue. He drew the following conclusions: ureteropyelographic study should be done in every case of renal trauma, after all acute

21. Harris, A.: Traumatic Rupture of Left Kidney: Case Report, *J. Urol.* 20:193, 1928.

symptoms have subsided. The time to investigate depends on the symptoms in the individual case and the judgment of the surgeon. More complete follow-up study should be carried out over a long period in every case to control secondary complication of infection and the formation of stone as far as possible. Chronic infection without obstruction might continue for long periods without symptoms sufficient to necessitate the consulting of a physician by the patient. Catheterization and renal lavage might be valuable in controlling infection. The reparative power of the kidney is remarkable. Open operation is indicated only in the exceptional, extreme case of renal injury, with uncontrollable hemorrhage. Infection following extravasation of urine or hematoma may require drainage. It is possible that an infected pouch, sinus or sac, not relieved by lavage, might be removed by open operation, the kidney being conserved at the same time. An accessory pouch seen in the pyelogram must be distinguished from solitary cyst of the kidney.

Suprarenal-Renal Heterotopia.—Caylor²² considered suprarenal-renal heterotopia as an anomaly of surgical and general significance, and defined it as the developmental inclusion of the suprarenal gland beneath the capsule of the kidney. Rests of suprarenal tissue are not included in this group, as they are usually made up of cortical cells, in contrast to true heterotopia in which both cortical and medullary elements are present. All or only a part of the suprarenal gland may be beneath the renal capsule.

Caylor found thirteen cases reported in the literature, and he added a fourteenth. A well developed woman, aged 34, apparently in good health, came to the Mayo Clinic for general examination. In the course of the examination, hydronephrosis of the right kidney was discovered. This kidney had a low functional value, while the left kidney functioned normally. The right kidney was removed through a lumbar incision. An accessory vessel to the right kidney was thought to have been a factor in causing the hydronephrosis. The kidney weighed 180 Gm. The hydronephrotic dilatation of the pelvis had apparently destroyed from 30 to 40 per cent of the parenchyma, and the anterior-superior surface of the kidney was partially covered with a yellow plaque, the suprarenal gland. As the capsule was stripped from the kidney, the gland was found intact beneath it, instead of in its usual situation in the perirenal fat. Duplication of the gland was not found.

Postoperative Statistics.—Hunt²³ reviewed the major surgical conditions arising in the kidney in cases observed at the Mayo Clinic during

22. Caylor, H. D.: Suprarenal-Renal Heterotopia: Report of a Case, *J. Urol.* 20:197, 1928.

23. Hunt, V. C.: A Review of the Surgery of the Kidney. *Proc. Staff. Meet. Mayo Clinic* 3:201, 1928.

the last six years. During this period, 1,640 operations were performed on the kidney. Nephrectomy was performed in 1,119 cases (68 per cent). In 157 of the cases, the disease was malignant; 11 patients died following nephrectomy, a mortality of 7 per cent. The remaining 962 nephrectomies were performed for benign disease, with 20 deaths, a mortality rate of 2 per cent. Five hundred and twenty-one conservative operations were performed on the kidney largely for lithiasis, with 8 deaths, a mortality of 1.5 per cent.

Renal stone was the most common surgical lesion, comprising 808 cases (49.2 per cent). Nephrectomy was performed in 287 (35.5 per cent) of the total number of cases of lithiasis. Seven deaths (2.4 per cent) occurred, as opposed to 1.5 per cent for the conservative operation. There were 521 conservative operations, such as pelviolithotomy (85 per cent), nephrolithotomy, or the combined operation.

Nephrectomy was done for renal tuberculosis in 305 cases (27.2 per cent). There were 6 deaths, a mortality of 1.9 per cent. In 336 cases (30 per cent of all the conditions that required nephrectomy) the operation was performed for pyonephrosis, pyelonephritis and hydronephrosis with infection.

One hundred and fifty-seven nephrectomies were performed for malignant disease of the kidney. Hypernephroma was the predominating lesion, occurring in 113 cases (72 per cent of all the malignant lesions); carcinoma, 20 cases (12.7 per cent); epithelioma, 17 cases (10.8 per cent), and sarcoma, 7 cases (4.4 per cent).

Operation was performed in 23 cases of fused or horseshoe kidney. There were 12 cases of renal lithiasis in which the stones were removed by pelviolithotomy.

Heminephrectomy was necessary in 6 cases of hydronephrosis; cysts were drained in 2 cases, exploration for pain was carried out in 2 cases, and accessory vessels were divided in 2 cases.

Braasch, in discussing Hunt's paper, stated that more than 30,000 cystoscopies had been performed during the same period. During these six years, there were a great many more patients with surgical lesions of the kidney who were not operated on for various reasons. Fully a third of the patients came with symptoms not referable to the urinary tract; possible involvement of the kidney was suggested only after careful examination. The mortality rate in nephrectomy performed for renal tuberculosis was 1.9 per cent, which is about the same as that in the total number of cases in which operations were performed on the kidneys.

Wildbolz recently quoted statistics of a series of 640 nephrectomies, showing a mortality of 2.8 per cent. He stated, however, that this number included a series of more than 100 cases in which operation

was performed without a fatality; this is further evidence that statistics based on a small number of cases are without value.

Attention was called to the high percentage of patients with renal lithiasis in whom it was necessary to remove the kidney. Braasch stated that the general practitioner is often largely responsible for this, since if he had insisted on investigating the cause of the patient's colic and if after the diagnosis of stone had been made he had insisted on operation, a conservative operation might have been possible. A conservative operation, of course, is best because of the possibility of bilateral lithiasis, if for no other reason.

URETER

Infection.—Kidd²⁴ suggested that the ureter should be examined carefully before nephrectomy is done, as in selected cases the removal of the major portion of the ureter, besides the kidney, will be found to give better results. In cases of hydronephrosis, if the obstruction of the ureter is in the pelvic region and the ureter as far as the obstruction is not removed, the portion remaining frequently causes trouble. The ureteral stump may remain infected and cause attacks of colic, fever and strangury, or a large infected pouch may form. In some cases, these attacks of dysuria and fever resulting from ureteral retention are relieved by the passage of purulent urine.

Some surgeons remove as large a portion of the ureter as possible when removing a tuberculous kidney; others consider that this step entails risk of the formation of an abscess or urinary fistula deep in the pelvis. Kidd believed that in cases of septic stones impacted in the pelvic ureter with a dilated atrophic ureter above, primary nephro-ureterectomy should be done. If the lumen of the ureter is not obstructed, complications will rarely arise even if the ureter is left in place. The inflamed and infected ureter will gradually atrophy and its contents become sterile. If the process of sterilization is delayed, it can be hastened by washing out the stump of the ureter. Kidd has noted that in many cases after operation for calculous pyonephrosis the stump of the ureter has become aseptic and has not given further trouble. On the other hand, if there is an obstruction between the site of the ligature and the bladder, trouble will probably arise in the stump of the ureter: the muscular wall will hypertrophy in an endeavor to get rid of the contents of the ureter, causing attacks of ureteral colic. The lumen of the ureter may become dilated and cause severe symptoms of urinary infection.

Kidd gave the following indications for primary nephro-ureterectomy: (1) in hydronephrosis, simple or infected, when the stricture is

24. Kidd, Frank: The Stump of the Ureter After Nephrectomy: Indications i - Primary Nephro-Ureterectomy, Brit. J. Surg. 16:22, 1928.

low in the pelvic ureter; (2) in pyonephrosis or atrophic septic or aseptic kidney secondary to a stone long impacted in the pelvic ureter; (3) in tuberculous pyonephrosis associated with inflammatory stricture in the pelvic ureter, and (4) in all other types of pyonephrosis associated with inflammatory stricture in the pelvic ureter.

In most cases in which Kidd performs primary *nephro-ureterectomy* he cuts down on the kidney from behind, and after it has been freed and its pedicle tied, he frees the lumbar ureter from its connections, taking care to tie all bleeding points, which may be numerous. The ureter can be burned across with a cautery, or the kidney and ureter can be left hanging out of the lower margin of the wound, which is then stitched up and the patient turned on his back. In the cases in which operation is more easily performed and in which the obstruction is high in the pelvic ureter, such as a stone, the ureter is then exposed extraperitoneally through a muscle-splitting incision for exposing the pelvic ureter, tied off with catgut below the point of obstruction, burned across, and with the kidney is drawn out from the wound in the back. If a drain is carried to the stump of the pelvic ureter, it should consist of a piece of rubber glove; tubes endanger the walls of the iliac vessels and should not be employed. If, on the other hand, the operation is difficult and the obstruction lies close to or even in the walls of the bladder, a better exposure can be obtained by turning the rectus muscle outward from near the median line below the umbilicus. Through this incision the ureter can be stripped extraperitoneally to the wall of the bladder; the numerous branches of the internal iliac and other vessels running to the wall of the pelvic ureter and bladder can be exposed and tied off, and the ureter can be completely removed. In some cases it has even been found necessary to remove a portion of the wall of the bladder, a step that is feasible through this incision.

Read²⁵ reported a case of empyema of the ureteral stump in a woman, aged 31. One week after hysterectomy, pus appeared in the urine. Three months later, a ureterovaginal fistula was found. The end of the left ureter was located in the fibrous tissue of the pelvis and transplanted into the upper angle of the bladder. The vaginal fistula healed, but foul pyuria persisted, and pain in the lower left quadrant and lower lumbar regions became increasingly severe. Six weeks later the pyuria was more severe, and left nephrectomy was performed. Pathologic examination disclosed general pyonephrosis. Two months after the nephrectomy the patient began to have severe, shooting pains along the course of the left ureter, radiating into the bladder. The attacks came on suddenly and lasted for from two to seven days.

25. Read, J. S.: A Ureteral Stump (Non-Tuberculosis) as a Source of Pyuria: Case Report, *J. Urol.* **21**:103, 1929.

Immediately after a colicky attack there was a large amount of pus in the urine: this was followed by relief. The urine never appeared cloudy except following an attack. At cystoscopic examination the left ureteral catheter entered for a distance of about 4 cm., and pus did not come from the stump on withdrawal of the catheter: this showed that there was no infection of the portion of the left ureter remaining after its incision at the time of hysterectomy. It was impossible to find the orifice of the transplanted ureter. The abdomen was opened, and many adhesions were found between the intestines and the abdominal wall; the omentum was adherent to the bladder at one point. All of the adhesions were freed, and on the upper left quadrant of the bladder the transplanted ureter was found extending across the pelvis for a distance of about 7.5 cm. At the point where the ureter left the pelvic wall below the brim of the pelvis, it was buried in dense scar tissue. The ureter was resected close to the bladder, and the remaining stump cauterized and inverted into the bladder. Due to the scar tissue, it was difficult to dissect the buried portion of the ureter. The remaining part of the ureter lying along the muscle bed was easily traced to its termination and resected. The part of the ureter resected was about 18.75 cm. long. It was contracted near its juncture with the bladder, where there was a portion of thin-walled dilatation. Within the cavity was thin purulent material which contained colon bacilli and staphylococci.

Stricture.—Campbell²⁶ stated that faulty drainage is the cause of infection of the urinary tract in infants as well as in adults. In 2,420 children coming to necropsy at Bellevue Hospital, ureteral blockage was found in 47 (approximately 2 per cent). Urinalysis or postmortem examination revealed infection in four fifths of these. In a large number of children with chronic pyuria, ureteral obstruction was found as the underlying lesion. Most of these acute renal infections ended favorably within two or three weeks, but there was a large group which resisted all forms of treatment.

Campbell reported a series of seventy-four cases of ureteral obstruction in infancy and early childhood. He used the classification of intra-ureteral or extra-ureteral, since these characteristics determine to a large degree the type of surgical procedure. The chief obstructions of and within the ureter itself were found to be strictures, including the formation of valves, calculi, kinks and anomalous conditions. Strictures, whether congenital or acquired, were the predominating ureteral obstructions in infancy. Congenital strictures were not infrequent and occurred at the two ends of the ureter, the ureteropelvic or uretero-

²⁶ Campbell, M. F.: Ureteral Obstruction in Infancy, *Am. J. Surg.* 5:445, 1928.

vesical junctures. In twenty-two patients, the blockage was bilateral; this condition was found in one instance in a 7 months' fetus. Campbell expressed the belief that the formation of stone is favored by urinary stasis and is most often associated with obstruction. Obstruction by acute ureteral angulations was associated with nephroptosis and renal ectopia, usually occurring at or near the ureteropelvic juncture. This type of blockage was characterized by marked hydronephrosis above and a relatively normal ureter. In cases of complete reduplication, obstruction rarely occurred at the point the ureter crossed in the pelvic cavity just above the bladder. Abnormal ureteral insertion may be found high in the renal pelvis with marked angulation or a lip valve which obstructs drainage. There may be ectopic insertion into the bladder, urethra, vagina or rectum.

Extra-ureteral masses were found to be predominantly inflammatory or neoplastic. Aberrant vessels usually passed from the lower renal pole to the aorta or vena cava. Chronic pyuria and pain in the loins were the usual symptoms.

The chief symptoms were hematuria, urinary frequency, dysuria, ureteral colic or dull aching in the loins with or without radiation. Chronic pyuria was the most constant symptom. In some cases palpation may reveal a renal mass, varying markedly in size. The onset may be acute and often follows an acute focal infection, but the urinary infection does not clear up within the usual time. In some cases pyuria was noted from birth, and in a few congenital ureteral obstruction with associated infection was noted at necropsy. The degree of obstruction is largely reflected by the temperature and pyuria.

Obstructive urinary lesions are characterized by dilatation, infection and renal destruction. Dilatation was usually more marked above the point of obstruction, but the inflammatory type was not infrequently observed below this point.

Relief of obstruction is the object of treatment. Dilatation of ureteral strictures afforded marked clinical improvement but bacteriologic cure was obtained in only three of Campbell's cases. He stated the belief that clinical improvement resulted from dilatation rather than lavage. Water in abundance is prescribed as the best medicine, and alkalis are of value when they promote diuresis. Medical measures are of value only when used with surgical procedures to relieve the obstruction. Early recognition and treatment save extensive renal destruction and often years of suffering or early death.

BLADDER

Tumors.—Hunt²⁷ stated that difficulty in evaluating reported results in favor of various methods of treating malignant tumors of the bladder

27. Hunt, V. C.: *The Surgical Treatment of Malignant Tumors of the Bladder*, J. A. M. A. **91**:1704 (Dec. 1) 1928.

is due to the lack of uniformity in classifying them according to the type of lesion, the degree of malignancy, and the situation and extent of involvement.

He found epithelioma, with varying degree of malignancy, in 95 per cent of the cases. Regardless of the site of the lesion, in a series of 480 epitheliomas graded on a scale of 1 to 4, 10 per cent were graded 1 (least malignant), 32 per cent were graded 2, 35 per cent were graded 3, and 23 per cent were graded 4, making a total of 58 per cent of a high degree of malignancy. The epitheliomas of the base of the bladder tend to be more highly malignant than those of the lateral wall or the dome. If all other conditions are equal, 10 per cent better results may be expected in the treatment for epitheliomas of the lateral walls and dome, simply because of the degree of malignancy.

The time of beginning treatment was found to have a significant bearing on operability and on the results of treatment. In a series of fifty-one cases in which the condition was too far advanced for any form of treatment, it was found that the average duration of symptoms previous to medical treatment was almost two years. Bumpus reviewed a series of 212 cases in which radium alone, or radium in conjunction with some other forms of treatment, was employed. He concluded that the use of radium alone is not successful in cases in which other methods of treatment cannot be used, that poor results are obtained when radium treatment is followed by operation, and that radium is most useful in connection with fulguration or operation. Hunt considered cautery excision as the method of choice for tumors of the lateral and posterior walls and dome of the bladder. Recurrence at the primary site of the lesion is less likely to follow.

The mortality rate of surgical procedures depends on the site of the tumor, the magnitude of the operation and, in lesions of the base of the bladder, on the method of disposing of the ureter. The mortality is lowest following the excision types of operation employed in the lateral walls and dome, and highest in segmental resection for tumors of the base with reimplantation of the ureter. Division and ligation of the ureter has proved the best method if the ureter is involved in the lesion or in extensive operable tumors of the base. In approximately 370 cases of epithelioma of the bladder, the results were dependent on the site of the tumor, the extent of the involvement and the degree of malignancy. In general, about 65 per cent of the patients with lesions graded 1 or 2 are living and well three years after operation, while 35 per cent of those on whom the radical operation was performed for lesions graded 3 or 4 showed equally good results. Approximately 73 per cent of the patients having tumors of the lateral walls or dome graded 1 or 2 and 42 per cent having tumors graded 3 or 4 are living three or more years afterward; 50 per cent of those having lesions

in the base graded 1 or 2 and 25 per cent having lesions graded 3 or 4 lived without recurrence for the same period.

Aschner²⁸ stated that several factors are responsible for the fact that vesical neoplasms are regarded as different from tumors elsewhere in the body and not subject to the usual mode of classification. There is a tendency for benign papillomas to implant themselves in other parts of the bladder and in the suprapubic wound after open operation, and also for new tumors to develop after the original tumor has been destroyed. Patients with papillomatosis or those who have been cured of papilloma may later have frank carcinoma of the bladder or metastatic phenomena with a malignant clinical course, and rare cases of papilloma with typical benign cell structure may show infiltration of the wall of the bladder.

The ordinary variety of papilloma is a soft, shaggy, villous tumor arising from the mucosa of the bladder by a well defined pedicle. The skeleton is formed by a delicate connective tissue core continuous with the submucosa of the bladder and containing blood vessels. The non-infiltrating type of papillary carcinoma may be pedunculated or sessile. It is usually indistinguishable cystoscopically or grossly from benign papilloma, from which a large percentage probably develop. The cell changes which indicate a malignant condition may be slight and limited to a small part of the growth, or marked and present throughout the growth. Nonpapillary carcinomas are characterized by their tendency to spread downward into the wall of the bladder and laterally under the normal mucosa, and often by ulceration and necrosis at the center of the growth. They seem to arise from the deeper cells of the mucosa, nests of which are not infrequently seen dipping downward in inflammatory processes, especially at the trigone and vesical neck.

Aschner concluded that in 97 per cent of the cases cystoscopic biopsy furnished the most reliable information as to the nature of tumors of the bladder. The failures occurred in multiple tumors and in papillomatosis. Prognosis cannot be made from biopsy alone in cases of malignant disease. The use of radium or operation, except on a debilitated patient, is indicated when a diagnosis of malignant disease is made in a case simulating papilloma. Aschner stated the belief that tumors of the bladder are benign or malignant, and that they may be classified in a manner harmonious with general tumor and clinical terminology. He did not consider cell grading alone as practicable for clinical purposes, and prognosis on such a basis does not coincide with the late results in his series of cases. Infiltration appears to be a more reliable guide to the extent of the lesion, and the site of the malignant tumor determines its resectability and influences prognosis materially.

28. Aschner, P. W.: *The Pathology of Vesical Neoplasms: Its Evaluation in Diagnosis and Prognosis*, J. A. M. A. **91**:1697 (Dec. 1) 1928.

The surgical procedure of choice when a diagnosis of carcinoma is made by biopsy is resection of the whole thickness of the wall of the bladder. Failure to do so, even in the case of pedunculated tumors, has often resulted in recurrence. Stalk invasion and tumor cells in blood vessels at the base cannot be detected by gross inspection. Only 20 of 137 papillary carcinomas were not infiltrating. Aschner expressed the belief that biopsy should always be made before radical operation on the bladder is undertaken, as other lesions may closely resemble neoplasm.

Stone.—Cabot²⁹ classified the cases of complicated stone in the bladder as cases in which the bladder is the seat of some other condition requiring surgical treatment. One of his fundamental principles when studying a patient with stone in the bladder is to determine whether there exists in the bladder some condition other than lithiasis which requires surgical treatment. If there is obstruction, diverticulum or other abnormality, the treatment for the stone becomes secondary to that for the other lesion.

Stone in the bladder may be treated by incision or by crushing and evacuation by instruments. Litholapaxy is the method of choice when it can be carried out satisfactorily. Indian surgeons are unanimously in favor of litholapaxy because convalescence is shortened, shock is lessened, and suprapubic scars are avoided. Cabot stated that there are several contraindications to litholapaxy. It should not be performed when there is disproportion between the size of the stone and the capacity of the bladder. When a large stone lies in a more or less contracted bladder, the movements of the instrument are limited; the amount of trauma resulting from many fragments is considerable and the time consumed in the operation, even if it is successful, is of disadvantage to the patient. In general a bladder that holds less than 125 cc. and contains a stone of considerable size will not be suitable for litholapaxy. Great surgical skill and experience may definitely modify this statement. Cabot considered the second contraindication to be cases in which the stone has as its nucleus a metallic foreign body or other substance which cannot be crushed. Before the development of the roentgen rays, it was difficult to determine with certainty the nature of the foreign body previous to operation. Litholapaxy should not be performed if the necessary instruments cannot be passed through the urethra. Stricture of the urethra is not a contraindication, since it can be readily divided by internal urethrotomy.

The group of borderline cases includes some of those in which the stone has a foreign body as its nucleus and a group in which the stone

²⁹ Cabot, Hugh: The Principles of Treatment of Stone in the Bladder. J. A. M. A. 91:1958 (Dec. 22) 1928.

lies not in the bladder but in a more or less dilated prostatic urethra. Some of the latter group may be considered as possibly satisfactory subjects for litholapaxy.

Diverticula.—Lower and Higgins,³⁰ from a study of the literature and their own experience, noted that the walls of diverticula vary in thickness, generally increasing with progressive inflammation of the diverticulum, although there may be a variation in different portions of the same diverticulum. The most common site of diverticula is proximal to one of the ureters, but no region of the bladder is exempt. Durrieux found records of fifteen diverticula situated in the trigone. Because of the quantity of fluid they contain, large diverticula tend to force their way backward, generally along the line of least resistance. Small diverticula usually lie between the bladder and rectum and, as they increase in size, extend laterally and upward. As a rule the orifice is quite small and entirely out of proportion to the size of the sac. The difficulty in emptying this type of diverticula makes them resistant to palliative treatment. The ureter may open directly into the diverticulum or may be incorporated in the wall of the diverticulum itself.

Diverticula are relatively infrequent in women. Rose's explanation of this is that in the female bladder, due to the absence of prostatic and seminal vesicle fixation, there is less loss of elasticity and less opportunity for diverticula to develop. Rathbun holds that all true diverticula are congenital and that the so-called acquired diverticula are only "exaggerated trabeculations." Diverticula may occur at any age, but they usually occur after the age of 50, during the period of prostatic obstruction.

The most common complications of diverticula are infection, calculi and tumors. Stagnation and infection are naturally conducive to the formation of stones, and these factors are usually present in varying degrees in such cases. Calculi in the diverticulum may be single or multiple. If they are multiple they may become faceted and lie close together, so that only the roentgen rays will show that more than one stone is present. When large stones are found in the diverticulum, they are usually associated with lithiasis in the bladder.

Diverticula do not cause definite symptoms, and the clinical picture varies with the presence or absence of infection. Many diverticula are discovered in cystoscopic examination in cases in which their presence has not been suspected, especially in hypertrophy of the prostate gland. The following diagnostic technic is used: Cystograms are made under the fluoroscope. After the bladder has been catheterized and drained, it is refilled with a solution of sodium iodide. A solution of from 10 to

30. Lower, W. E., and Higgins, C. C.: *Diverticula of the Urinary Bladder with Report of One Hundred and Ten Cases*, J. Urol. **20**:635, 1928.

17 per cent may be used without apparent irritation of the bladder. As the bladder is gradually filled, a close watch is kept for the appearance of irregularities which might be caused by hypertrophy of the prostate, tumors of the bladder, trabeculations or diverticula.

The present trend of treatment for diverticula is toward radical excision of the entire sac. As diverticula are usually associated with obstruction, the cause of the latter must also be removed in order to secure a satisfactory end-result. Lower operates under spinal or sacral anesthesia; in the case of an apprehensive patient, he adds analgesia with nitrous oxide and oxygen. A median suprapubic incision is made and carried down to the bladder. After the peritoneum is stripped back, the bladder is opened. Exposure of the interior of the bladder is secured with flexible retractors and a Cameron light. The diverticulum is located, and from its size and position the mode of procedure is determined. If the extravesical approach is used, the collapsed diverticulum is first converted into a solid or semisolid tumor by packing it with a gauze tape. Lower then dissects down outside the bladder, severing the attachment of the diverticulum and closing the opening into the bladder. It is important that the closure of the bladder at the point of removal of the diverticulum be made with good muscular apposition, the walls being inverted if possible so as to leave a slight ridge on the inner surface of the bladder rather than a depression at the point from which the attachment of the diverticulum was removed. Such a depression might serve as a starting point for recurrence of the diverticulum.

In forty-five cases of the series, the diverticulum was excised. There were three operative deaths (7 per cent). Twelve of the patients have not been traced since operation. Five patients have died since operation. Of the remaining twenty-one patients, observed for periods varying from six months to fourteen years, the average postoperative period was four years; marked improvement was noted in twelve; in nine, there was complete relief of symptoms.

Prognosis is usually favorable if radical operation is performed early and before renal impairment has become marked. In cases in which a malignant growth is present, the prognosis must be guarded.

Fistula.—Farman and Thompson,³¹ before attempting an operation for a vesicovaginal fistula, follow the principle of correcting any cystitis or other intravesical complication. Such a procedure presupposes a thorough cystoscopic examination of the bladder, determination of the exact size and situation of the fistula, and its relationship to the ureters. Small fistulas involving the lower part of the vesicovaginal septum

31. Farman, Franklin; and Thompson, R. C.: *Vesicovaginal Fistula: Etiology, Surgical Principles of Repair and Technique of Suprapubic Transvesical Operation*. J. Urol. 20:663, 1928.

usually are more readily accessible and lend themselves better to proper dissection and closure by the vaginal operation or one of its modifications. Fistulas high in the vagina are difficult to close, and failure is frequent by the vaginal route.

In repairing vesicovaginal fistula, a proper exposure of the operative field is made, as success depends on accurate and complete closure with well placed sutures in healthy tissue. All scar tissue is dissected from the thick vesicovaginal septum until the denuded, raw surfaces are soft and plastic. This will usually leave an opening two or three times the size of the original fistula to be closed by suture. Mobilization of the bladder is one of the most significant steps in the technic of repair; it permits the viscus to return to a more normal position (retraction upward and forward), and tends to separate the opening in the bladder from the opening in the vagina. It is necessary to secure a tight non-leaking closure that is urine proof. The method of suturing should be adapted to the size of the openings, elasticity of the tissues and accessibility. Circular, purse-string, lockstitch or continuous through-and-through sutures may be used. Chromic catgut generally is required for the main sutures. Opinion varies as to the necessity, method and length of time advisable for drainage of the bladder during healing. The majority of surgeons using the vaginal route for repair have drained the bladder after from six to ten days with a Pezzer catheter. A few have performed suprapubic cystostomy. The idea of drainage by catheter or cystostomy is to immobilize, during healing, the previously mobilized floor of the bladder and to relieve pressure on the line of suture.

The success of operation depends partially on skilled postoperative care, for any complication may be the undoing of the repaired fistula. Infection of the part usually means failure, but it is well known that tissues in this region possess a high degree of healing properties and local resistance. It is important to prevent spasm of the bladder, unnecessary movement or straining, restlessness, constipation, and contamination of the pelvic parts. Mayo and Walters expressed the belief that the success of repair depends on healing in the line of suture and accurate closure of the openings in the bladder and vagina. Some operators suture the openings at right angles to each other.

Paralysis.—Cahill³² observed that in conditions causing paralysis or destruction of the spinal cord, retention of urine began at once and continued until the bladder was greatly distended and showed in the lower part of the abdomen as a large ovoid tumor. The bladder still retains the power of contraction and should be properly stimulated so that it will gradually assume the power automatically to relieve itself.

32. Cahill, G. F.: Treatment of Bladder Paralysis Due to Non-Tabetic Spinal Cord Lesions, *Am. J. Surg.* 5:442, 1928.

In treating patients with paralysis of the cord with resulting urinary retention, Cahill does not perform catheterization but allows the bladder to fill for twenty-four hours and then forces the relief of the bladder by pressure excited on the fundus. When the bladder can be clearly and easily felt, the right or left hand is placed sidewise across the fundus and the ulnar side pushed above the fundus as far as possible into the abdomen. The fundus is then cupped or grasped and pressure exerted by pushing down against the pelvic opening. The urine may not appear for one or two minutes after pressure and then may be voided only in a small irregular stream. Pressure is then applied every two hours, each time the amount of urine obtained slowly increasing and the pressure required decreasing. It usually takes from six to ten days before the bladder empties well behind the symphysis and several weeks before it empties completely. If possible, Cahill instructs patients how to apply the pressure themselves, and sometimes they are able to hasten the emptying of the bladder by applying their own increase of abdominal tension by breathing.

If there is infection, catheterization is instituted but only until the infection has subsided.

Cysts.—Altmann³³ stated that cysts of the posterior wall of the bladder, especially in the prostate gland, are comparatively uncommon. Eliminating echinococcus and dermoid cysts, Meyer considered the following as etiologic possibilities: (1) fetal inclusion of the prostatic utricle due to epithelial adhesions, that is, a sealing off of the terminal portion with a subsequent cystic dilatation of its lumen as well as a disturbance in the development of the mullerian duct; (2) cystic dilatation of the prostatic and trigonal glands; (3) abnormal persistence of portions of the mullerian duct derived from its terminal segment, and (4) offshoots from the seminal vesicles and ducts. On account of the frequent association of the cysts with the utricle, Altmann favored the first hypothesis. Hypotheses regarding the association of neighboring glandular structures may be assumed. The second group comes in this classification.

A case of a man, aged 19 years, is cited which could be classified in the third or fourth group. Necropsy revealed marked hydro-ureter and hydronephrosis on the left side, associated with the seminal vesicles and vas. A large piece of adjacent tissue and wall of the bladder was removed in order to study the case thoroughly. The inner wall of the cyst was composed of a double layer of cubical epithelial cells. The cyst was entirely closed off from adjacent tissues.

33. Altmann, Franz: Zur Kenntnis der Cysten an der hintern Blasewand beim Menne, *Ztschr. f. urol. Chir.* 24:438, 1928.

There are only nine reported cases in the literature, in all of which the cysts were small, about 2 cm. in size, and were found at varying ages, from birth to old age. Six were in the median line just above the prostate gland, and three were situated below the prostate gland and medially to the vas. Most of the cysts were oval or pear-shaped. Histologically, all cysts were lined with cubical epithelium. In two cases, including that of Altmann, muscle fibers were found in the wall of the cyst. This was interpreted as meaning an association with the ductus deferens.

Exstrophy.—Judd and Thompson³⁴ stated that the ultimate cause of exstrophy of the bladder is not known, but the existing theories collectively purpose that it results from mechanical rupture, pathologic lesions, or defective embryonic development. Histologic studies reveal that the structure of the bladder in cases of exstrophy is usually unlike that of the normal bladder, and glands have been constantly observed. There are usually varying degrees of local inflammation, the result of mechanical and chemical irritation and infection. Associated ascending infection is common, and death usually is caused by toxemia of infection or of renal insufficiency.

Judd and Thompson described 2 cases of carcinoma complicating exstrophy of the bladder, making a total of 20 reported cases. Adenocarcinoma was reported in 15 cases and squamous cell carcinoma in 2; a histologic report was not made in 3 cases. Although adenocarcinoma is of comparatively rare occurrence in the normal bladder, it is the type which most commonly occurs in exstrophy of the bladder. Nineteen (2.19 per cent) adenocarcinomas were found among 867 tumors of the normally developed bladder at the Mayo Clinic. Of the 20 reported cases, 12 occurred in men and 7 in women; in 1 case, the sex was not mentioned. Two occurred in the third decade, 5 in the fourth, 9 in the fifth, 3 in the sixth, 1 in the seventh. Surgical treatment was employed in 10 of the 20 cases. In 3, simple extirpation of the bladder was performed. In 1 case, transplantation of the ureters by the Mayo method preceded removal of the bladder. The patient died two years after operation from metastasis. In 2 cases cited by Judd and Thompson, the patients are alive and well three, and six and a half years respectively, after operation. In 3 other cases transplantation of the ureters into the colon was performed. One of the patients died eight days later from uremia following ascending renal infection. In the other 2 cases, resection of the bladder was performed secondarily.

Vesical Neck.—Herbst³⁵ observed that although the symptoms of fibrosis of the neck of the bladder may not be marked until adult life

34. Judd, E. S., and Thompson, H. L.: Exstrophy of the Bladder Complicated by Carcinoma, *Arch. Surg.* **17**:641 (Oct.) 1928.

35. Herbst, R. H.: Fibrosis of the Vesical Neck, *J. A. M. A.* **91**:1614 (Nov. 24) 1928.

or later, a surprisingly large number of these patients give a history of disturbances of the bladder in childhood.

The appearance of the bladder, as well as the symptoms of fibrosis, is quite different from that found in other obstructive conditions. Fibrosis of the vesical neck is generally characterized by a small contracted bladder with massive thickening and hypertrophy of the wall, instead of a large dilated bladder with moderate hypertrophy of the muscle coat. The symptoms of fibrosis may be classified as those referable to the bladder and those produced by changes in the upper urinary tract. The bladder is usually small and often contracted because of the hypertrophy of the muscular wall, a condition which frequently causes an active form of incontinence, in contrast to the passive overflow type seen in other forms of obstruction. Urgency and frequency of urination are prominent symptoms. Complete retention is infrequent due to the powerful contraction of the hypertrophic wall of the bladder, but regurgitation to the upper urinary tract is more pronounced than in most other types of obstruction. On rectal examination, the prostate gland is usually about normal in size and in consistence. If an instrument is introduced into the bladder, resistance may be encountered immediately at the neck of the bladder, which as a rule is easily overcome. In uncomplicated cases there is marked trabeculation, the trabeculae being heavy with deep cellules between them. The vertex of the bladder is more contracted than the lower part, causing the formation of a dome which at times may be mistaken for a diverticulum.

Herbst stated the belief that the degree of retention and the impairment of the renal function should be determined so as to distinguish between the cases of fibrosis in which the condition can be corrected without drainage and those in which drainage is required. He considered some type of drainage by catheter to be preferable to preliminary cystostomy because of the difficulty encountered later in obtaining good exposure of the neck of the bladder, which is essential to thorough removal of the fibrotic neck. Some form of transurethral or punch operation is the method of choice in the milder types of fibrosis, particularly those in which the lower segment of the internal urethral orifice is most involved.

Mucous Glands.—Edelman³⁶ reported two cases from Mount Sinai Hospital in which intestinal-like mucous glands were found in the urinary bladder. Both patients complained of frequency, dysuria and hematuria, suggestive of new growth or intense cystitis. One gave a history of having passed gravel.

³⁶ Edelman, Leo: Muciparous Glands in the Mucosa of the Urinary Bladder, *J Urol*, 20:211, 1928.

Some observers deny that mucous glands exist in the urinary bladder; others admit their presence; others interpret them as aberrant prostatic or urethral glands. The cases reported in the literature showing lesions containing "intestine-like" mucous glands have their origin ascribed to misplaced embryonal intestinal glands, to embryonal rests, to proliferation and metaplasia of the surface epithelium (Enderlen), to proliferation of lesions in cystitis cystica due to an inflammatory process (Stoerk and Zuckerkandl), and to proliferation of mucous glands normally present in the mucosa (Bridoux).

The lesions do not cause distinctive symptoms. The patients usually complain of frequency, dysuria and hematuria. Therefore, the diagnosis can be made only by microscopic examination of the tissues removed. The treatment is either excision or destruction with the cautery. The persistence of these glands may possibly be the basis for the development of adenoma or adenocarcinoma.

PROSTATE GLAND

Hypertrophy.—Davis³⁷ summarized the immediate and later results in a series of 176 consecutive cases in which perineal prostatectomy was performed under sacral anesthesia in an attempt to determine the immediate mortality and the percentage of satisfactory functional results. There were 3 deaths (1.7 per cent) in his series. The average age of the patients was 70; 16 were more than 80 years of age, two of these being 88.

Davis stated that the factors instrumental in reducing the mortality rate of prostatectomy are preliminary drainage, sacral anesthesia and careful hemostasis. Good hemostatic control is particularly important, as many deaths may result from hemorrhage due to infection secondary to lowered resistance. Prostatectomy may be made an almost bloodless procedure as the result of the opportunity for deliberateness in controlling individual bleeding points by suture and ligature which is afforded by the employment of sacral anesthesia, and the use of an inflated hemostatic bag to control hemorrhage during the first few postoperative hours. The anesthesia used in all of Davis' cases was sacral block, including injection through the sacral hiatus (caudal anesthesia), as well as through the first, second and third sacral foramina on either side. This type of anesthetic has eliminated the problem of anesthesia for prostatectomy in old and debilitated patients. It is easily and simply administered, is almost uniformly efficient, and does not cause complications. There was not a death nor a reaction of consequence in his entire series. Hemorrhage should be treated as an

37. Davis, Edwin: Perineal Prostatectomy Under Sacral Anesthesia, J. A. M. A. 91:1618 (Nov. 24) 1928.

emergency measure and should be checked by mechanical means, even though it necessitates a secondary operation.

Davis expressed the belief that functional results should be as significant, if not more so, than the immediate mortality rate. Good functional results are dependent on accuracy in preoperative diagnosis as well as on proper operative technic. On the basis of his late observations and on the assumption that there has been a proper diagnosis, preparation and operative technic, Davis made a conservative estimate that one may expect 80 per cent of satisfied patients following prostatectomy and 15 per cent of fairly satisfied patients.

Lewis³⁵ employed perineal prostatectomy exclusively for several years, but for the last fifteen years he has obtained better results with the suprapubic method. He pointed out that, even though Davis had a low immediate mortality rate in his series, in 36 of 100 patients traced the condition remained uncontrolled, while six cases of fistula resulted. He believed that these should not have been present in any of the cases in which prostatectomy was performed.

Thomas,³⁵ stated that the mortality rate of Davis will not be improved for a long time. He expressed the belief that Davis should not be permitted to convey the idea that in all cases of prostatic hypertrophy operation should be performed by the perineal route. If those who practice this method exclusively would give more attention to the route and make the type of operation dependent on the pathologic changes present, not only would the present mortality rates be lowered but improvement would attend the morbidity results. It is Thomas' belief that there is something wrong with urology when some of the leading exponents contend that prostatectomy should always be done suprapubically, while others insist that it should be done perineally.

Livermore³⁵ has favored the suprapubic method of prostatectomy because he has obtained better results and considers himself more skilled in it. It is his opinion that the choice of technic is a personal matter.

Foley³⁵ stated the belief that it is useless to attempt a comparative appraisal of perineal and suprapubic prostatectomy because of the prejudice of advocates of the two operations. He considers perineal prostatectomy a technically difficult procedure, the main difficulty being the proper division of the recto-urethralis muscle. If technical faults on the part of the operator are not considered, the perineal operation regularly gives a functional result as good as it is possible to obtain by the suprapubic approach. A poor functional result means an incorrect dissection. To him there is no latitude between the proper dissection which will give a perfect functional result and an improper one resulting in incontinence or injury to the rectum.

³⁵ In discussion on Davis (footnote 37).

Carcinoma.—Roberts³⁰ reported three cases of carcinoma of the prostate. In the first case he found metastasis to the skull, the left clavicle, the left fifth rib, and the abdominal lymph drainage limited to the pelvic vessels. The outstanding features of the second case were the involvement of the upper dorsal vertebrae and the fourth left rib, together with the absence of any involvement of the abdominal lymph vessels above the level of the second lumbar vertebra.

A study of these cases, together with others of a similar nature showing involvement of the skull and upper dorsal region, suggested the possibility of a constant path of dissemination from the primary growth in the prostate gland. On theoretical considerations the spinal canal was regarded as a possible route, and it was further indicated by the widespread involvement of the pelvic bones sometimes seen in these cases. It was therefore decided to examine the spinal column in all cases in the future. In Roberts' third case, necropsy serves to support the contention. At necropsy the spinal laminae, with the ligaments, were removed in one piece from the cervical to the lower lumbar region, and at once plaques of growth were seen to involve the whole length of the ligamenta subflava and the intraspinal surface of the laminae. Both the dura mater and its contents and the posterior common ligament appeared to be normal. There was an almost continuous direct spread of growth on the intraspinal surface of the dorsal wall of the spinal canal from the sacral to the cervical region, whereas the abdominal lymph spread had extended only as far as the upper lumbar region. It is interesting to note that the thoracic duct was uninvolved throughout its thoracic course. Histologic section of the temporal bone showed marked invasion by carcinoma cells of the same types as those found in the pelvic lymph glands and prostate gland. A section of the lamina in the upper dorsal region also showed columns of carcinoma cells in the spaces of the connective tissue of the ligaments and periosteum of the laminae; some of these columns appeared to be surrounded by a layer of endothelial cells suggesting lymph vessels, while others appeared to lie in close contact with the connective tissue fibers and cells. The spinous process and lamina were also extensively involved.

Roberts discussed the usual methods of the spread of metastasis and suggested that another route plays an important (and perhaps the most important) part in the distant dissemination of malignant cells from the prostate gland. This path consists of the lymphatic vessels and tissue spaces of the spinal laminae with their associated ligaments. Structurally, the ligamenta subflava consists of elastic tissue fibers with a network of lymph spaces both between and on the surface of the fibers

39. Roberts, O. W.: Some Notes on Carcinoma of the Prostate; Including Evidence of an Intraspinal Route of Dissemination, *Brit. J. Surg.* **15**:652, 1928.

of which they are composed; also, the interspinal ligaments have loose connective tissue between the fibrous framework. The path by which the cells reach the spinal canal is at present unknown, but in a recent postmortem examination two likely pathways were noted. One path is by the lymph drainage of the prostate gland to the sacral lymph glands; these glands lie near the anterior sacral foramina and, in this case, were found to be extensively invaded. It is possible that permeation of lymph vessels by the carcinomatous cells may obstruct the flow of lymph from the sacral glands to the iliac and para-aortic vessels and may lead to an increase of flow through the vessels linking up the intraspinal with the intra-abdominal lymph vessels. Along this path, the malignant cell would be able to grow and permeation or emboli occur readily. The other path noted was the loose connective tissue lying on the surface of the levator ani and coccygeus muscles; a tongue of new growth was found passing from the prostate gland toward the anterior sacral foramina in this tissue. Histologically, the growth appeared to be due to infiltration of loose tissue rather than to lymphatic permeation, but further sections are necessary before this question can be decided. The pelvic nerves appeared to be free from invasion, as did the blood vessels. By this intraspinal route, rapid dissemination to distant parts of the body is feasible. The vertebrae, ribs and skull are accessible to the invading cells, and the involvement of the bone-marrow of these bones may account for the extreme anemia and asthenia in cases in which metastasis is so widespread. Theoretically, one would expect changes in the lymph flow in the upper dorsal region, since the main lymph vessel and its branches in this region are subject to the suction action of the respiratory movements of the thorax and of the negative pressure in the great veins. In this way permeation of vessels in the upper dorsal region, especially of the left side, would be explained.

Wildbolz⁴⁰ operated on forty patients with carcinoma of the prostate. Three (7.5 per cent) of the patients died from the operation; thirteen (30.2 per cent) had either multiple metastasis or local recurrence from eighteen months to three years after operation; four died from one to three years after the operation of other diseases, without evidence of malignant recurrence; twelve lived more than three years after the operation, and were completely free of the trouble and without evidence of recurrence; these might be said to have had an operative cure. One patient died of pneumonia nine years after operation, two died of heart trouble six years after operation, and one died of apoplexy five years after operation. Five patients were completely well at the time this paper was written, more than three years after operation. In all of these cases, the diagnosis was made by histologic examination.

TESTES, EPIDIDYMIS AND SEMINAL VESICLES

Carcinoma.—Scholl⁴¹ reported the case of a man, aged 22, who came for relief of pain in the right inguinal region and because of swelling of the right testis, which had been severely injured while he was playing football fourteen months before. For six months there had been a gradual swelling of the right side of the scrotum, until it was about twice its normal size. The testis was smooth, rounded and slightly larger than normal. The epididymis could be identified easily; it was distinctly separate from the testis and markedly enlarged.

At operation the testis was not increased in size and apparently was not diseased; it was smooth, rounded and a normal bluish white. The epididymis was greatly enlarged and irregular in contour. It was readily separated by sharp dissection from the testis. There was no invasion of the testicular substance, which was normal in size, shape and consistence. The epididymis was nodular and reddish. The vas was separated and a short segment removed with the epididymis. Microscopic examination revealed the growth to be malignant and the testis, the surrounding coverings and the cord were removed. Three months after operation, a mass 2 cm. in diameter was found below the lower angle of the incision. At a second operation, the fascia of the external oblique muscle was opened and the stump of the cord excised at the internal ring. The cord, tumor and all the surrounding tissues, including the inguinal glands and subcutaneous tissue, were then removed. Enlarged inguinal glands were not found. The wound healed well, and the patient was given roentgen treatment over the lower portion of the abdomen and the area of recurrence.

Four months after the operation the patient became short of breath and cyanotic. Examination revealed a large amount of fluid in the right side of the chest. A needle was inserted into the base of the left pleural sac, and 4 liters of blood-stained fluid was withdrawn. Roentgen examination of the chest after removal of the fluid revealed a mass about 6 cm. in diameter in the region of the hilum of the lung. One week later a second tapping was done, and 2 liters of fluid was removed. After that the patient's chest was tapped about once every ten days, from 2 to 3 liters of fluid being removed at each tapping. The pathologist's diagnosis was adenocarcinoma of the epididymis.

Tuberculosis.—Young⁴² presented an analysis of twenty-two cases of genital tuberculosis in which he operated at least five years ago. In six cases nephrectomy was carried out in addition to the radical removal

41. Scholl, A. J.: Primary Adenocarcinoma of the Epididymis: Report of a Case, *J. A. M. A.* **91**:560 (Aug. 25) 1928.

42. Young, H. H.: Brief Note on Ultimate Results of Radical Operation for Tuberculosis of the Seminal Tract, *J. Urol.* **19**:679, 1928.

of the seminal tract. In several of these cases, severe urinary symptoms with involvement of the seminal vesicles and epididymis had developed in the tuberculous process. In most of the cases the condition of the patient was poor, with local involvement extending to the seminal vesicles and the prostate gland, as well as to the epididymis on one or both sides and sometimes to the testes. In five of the early cases only one seminal vesicle and one lobe of the prostate gland were removed, along with one side of the epididymis and one vas. Recurrence of tuberculosis in the remaining side of the epididymis has led Young to practice bilateral vesiculectomy and ampullectomy in cases of this type, with markedly improved results in eliminating subsequent involvement of the remaining epididymis. The prostate gland was involved close to the urethra in most of the cases. In four patients a persistent urinary fistula was present, leakage occurring only during urination, indicating that it came from the prostatic urethra and not the bladder. Patients were greatly relieved of pain, frequency of urination and hematuria by the operation of removal of the tuberculous seminal tract, even when pulmonary tuberculosis was present and was the cause of death. In five of six cases in which both vesiculectomy and nephrectomy were done, pulmonary lesions were present but at the last report only one patient had died.

In regard to operative technic, Young has found the use of caudal anesthesia usually successful in securing a painless procedure until the deep portions of the seminal vesicles and vas are attacked, and then local infiltration anesthesia is usually satisfactory in relieving pain.

There were no operative deaths. Six deaths are known to have occurred during the five years or more since operation: all of these patients had pronounced pulmonary involvement before operation. Fourteen patients (67 per cent) have been traced and found in good condition from one to twelve years after operation (nine, more than five years; one, four years; three, three years and one, one year). Statistics show that seminal vesicles are involved in most cases of genital tuberculosis.

Barney and Colby⁴³ stated that genital tuberculosis takes its origin from either coexistent or healed extragenital lesions, which are usually found in cases of genital tuberculosis. In a large percentage of cases in which the epididymis is involved, clinical examination shows involvement of the prostate gland and seminal vesicles. There are two views as to the incipency of this disease: that it is primary in the epididymis, and that it is primary in the seminal vesicles. The bacillus of tuberculosis may be transmitted from the epididymis to the seminal vesicle

43. Barney, J. D., and Colby, F. H.: *The Treatment of Genital Tuberculosis in the Male*, J. Urol. 19:657, 1928.

with the stream of secretion, known as the "descending route," or the infection may follow the blood stream or "ascending route." Most writers favor the former route.

The lesions of the epididymis usually begin in the globus minor, and the seminal vesicle on the same side is the one usually involved. Possibility of involvement of the second epididymis is decreased by removal on the side first affected, and the excision of the vas on the apparently healthy side aids in curtailing the spread of the disease to that side. The testis may not become affected even after years of contact with a tuberculous epididymis.

Treatment may be surgical or medical. Radical operation involves the removal of the seminal vesicles, prostate, vas and epididymis, together with the testis if it is involved. Medical treatment may include minor operations but consists primarily of the administration of tuberculin, heliotherapy, roentgen rays and ultraviolet rays and does nothing more than arrest the progress of the disease in some instances, often without improving the general condition of the patient.

In the author's experience, epididymectomy resulted in as low an operative mortality and good results in general as the more radical operations. It has been frequently observed that following epididymectomy the disease found before operation in the seminal vesicles and prostate gland not only ceases to progress but actually retrogresses to the point of clinical cure. This observation gives support to the belief that the disease begins in the epididymis.

Many patients with genital tuberculosis eventually die of tuberculosis of the lung or of miliary tuberculosis, which is probably attributable to the original lesion in the lungs or bronchial lymph glands rather than to areas of disease which conservative operation or medical treatment has left behind.

Wildbolz⁴⁴ stated that acute tuberculous epididymitis is much more significant than is generally believed. In about 25 per cent of all the patients with tuberculous epididymitis that he saw the condition began with an acute period similar to that caused by infection with gonococci, colon bacilli or staphylococci. This acute onset occasionally leads to a false sense of security, and valuable time is lost. In order not to make serious mistakes, it is necessary always to remember that tuberculosis may produce acute epididymitis.

It is usually easy to distinguish acute tuberculous epididymitis from gonorrheal or other epididymitis. Acute tuberculous epididymitis is produced only in the presence of high allergy. This high allergy is only found if the patient has, at the moment, a virulent tuberculous infection,

44. Wildbolz, Hans: Nonspecific Chronic Epididymitis and Tuberculous Epididymitis, *Proc. Staff. Meet. Mayo Clinic* 3:169, 1928.

so that in most cases of acute tuberculous epididymitis tuberculosis of the bladder, kidney, prostate, seminal vesicles, lungs or joints will be associated. If the diagnosis does not seem clear, one must observe the patient a short time. In the case of gonorrheal infection or other infection, the infiltration of the epididymis will regress after a few days. In a case of acute tuberculous epididymitis diminution of the symptoms of acute inflammation will be noted, but the infiltration will not regress and will perhaps progress. This slow regression of infiltration must always be a warning that the epididymitis may be tuberculous.

In about 25 per cent of the cases the tuberculous infection is primary in the epididymis, and the epididymis should be removed. In more than 150 cases of epididymectomy which Wildbolz could trace for many years, there was no recurrence of tuberculosis of the testis when it was not present in the testis at operation. Wildbolz expressed the belief that the best way of preventing tuberculosis of the testis is removal of a tuberculous epididymis as soon as possible, and he does this even in the acute period of the infection. It is slightly more difficult to remove the epididymis in the acute stages, but the acutely inflamed epididymis can be detached and removed separately. As soon as it has been determined that the epididymis is tuberculous, either chronically or acutely infected, it should be removed at once. In 90 per cent of the cases, there will never be further passage of spermatozoa. Consequently, there is no reason for not removing it.

Wildbolz has tried the various conservative methods of treatment, such as tuberculin, roentgen rays and heliotherapy. Even after employing conservative nonsurgical methods for one or two years, he was not certain that the recovery was complete. He has removed the epididymis following treatment by conservative methods for from three to seven years, and has found many tubercles and virulent bacilli. He believes that in the reports of healing in cases of tuberculous epididymitis after roentgen or tuberculin treatment in a few weeks or months the condition was not tuberculous epididymitis but chronic nontuberculous epididymitis, a disease not yet universally known.

Seminal Vesiculitis.—Wassiljeff⁴⁵ stated that most of the literature deals only with the clinical diseases of the seminal vesicles and little with their pathologic anatomy. The seminal vesicles are often mentioned in association with various disease processes. Using the material from 120 necropsies, Wassiljeff attempted to determine the frequency of vesicle changes due to disease and age.

The collected material was divided into the following groups: six cases of syphilis (syphilitic mesa-ortitis with aneurysm and progressive

45. Wassiljeff, A. A.: Ueber die pathologischen Veränderungen der Samenblasen (auf Grund des Leichmaterials), Ztschr. f. urol. Chir. 24:502, 1928.

paralysis); ten cases of nonspecific diseases of the vascular system, arteriosclerotic and contracted kidney, and arteriosclerosis of the cerebral arteries; thirty-one cases of all types of tuberculosis, that is, of the lungs, kidneys, genital organs—acute, miliary and chronic; thirty-six cases of all types of acute and chronic septic processes, such as endocarditis and peritonitis, and also the acute infectious diseases; twenty-six cases of malignant growths of the various organs, and eleven cases of miscellaneous growths and diseases.

Changes in the seminal vesicles were grouped as follows: comparatively pure types of changes in the seminal vesicles due to age; changes which are on the borderline between those due to age and those due to pathologic conditions, and pure pathologic changes.

Wassiljeff stated that changes of the seminal vesicles due to age show themselves in thickening of the septums of the vesicles, in diminution of their lumen, in substitution of the muscle fibers by connective tissue, in deposition of pigment in the epithelial cells, and in complete atrophy of the vesicles. The vascular system of the seminal vesicle capsule is early affected with arteriosclerotic changes. Deposition of pigment in the cell elements of the walls of the vesicles and the formation of cystlike diverticula may also be attributed to changes due to age and is apparently aided by the cachectic diseases. The formation of cysts is probably instituted by inflammatory processes, increasing with the addition of connective tissue, and occasionally there may be obliteration of the lumen of the vesicle. Inflammatory processes were frequently found in the seminal vesicles, such as metastatic pus vesiculitis, chronic and acute catarrhal vesiculitis, chronic fibrous vesiculitis (dilated or atrophic vesicles) and chronic perivesiculitis.

Chronic inflammation of the vesicles was demonstrated in 47 per cent of the septic cases, in 80 per cent of the syphilitic cases, and in 19 per cent of the tuberculous cases. Tuberculous changes of the vesicles were found in 22.8 per cent of the cases of general tuberculosis. The calcification of the contents of the seminal vesicles results occasionally in cases of tuberculosis. In cases of malignant growths of the prostate gland and the bladder, infiltration of the walls of the seminal vesicles was observed. Metastasis from tumors of distant organs is not infrequently found but is usually overlooked, since macroscopic changes are not sharply outlined.

URETHRA

Carcinoma.—Robb,⁴⁶ in reviewing the literature, found that the lesion usually occurs deep in the bulbous urethra where it may arise

46. Robb, J. J.: Cancer of the Male Urethra: Report of Two Cases with a Short Survey of the Subject, *Brit. J. Surg.* **15**:605, 1928.

from Cowper's glands or from other glandular structure. The case reported by Robb is apparently the first one on record in which cancer of the urethra originated in a stricture. The patient, a man, aged 59, contracted gonorrhea at the age of 21. For six years he was treated for a stricture which had been dilated on 111 occasions, a total of 477 instruments having been passed. Eventually, it became impossible to pass instruments, and he was admitted to the hospital. A hard stricture could be felt at the penoscrotal angle, with a nodule about the size of a "small marble" on its upper and left side. The stricture was excised, and microscopic examination of the tissue revealed a transitional cell carcinoma. Further operation was refused at the time, but two and a half months later, on recurrence of the nodule, the patient consented to amputation. A case was reported also of a man, aged 69, who was admitted to the hospital with a suprapubic fistula following cystotomy. There was a dense mass in the perineum. A specimen removed revealed transitional cell carcinoma.

From seventy-six case reports from the literature in which evidence as to the nature of the tumor was available, the following list was compiled: squamous cell carcinoma, 73 per cent; columnar cell carcinoma, 1.5 per cent; papillary carcinoma, 3.5 per cent; adenocarcinoma, 21.2 per cent (from Cowper's glands), and transitional cell carcinoma, 1.3 per cent.

Great difficulty was experienced in determining the site of these tumors, owing to the insufficient data in the recorded cases. Robb, therefore, referred only to the sixty-one case reports found by Diehle and classified as follows: membranous urethra, thirty-three; pars cavernosa, twenty-six; and fossa navicularis, two. Recognition of the high percentage of squamous cell carcinomas which occur in the male urethra casts doubt on the small number originating in the fossa navicularis. Descriptions are inadequate to make this opinion decisive, but in a large proportion of cases in which the anterior part of the pars cavernosa is involved, the condition may originate in and around the fossa navicularis and thence spread backward.

Carcinoma of the urethra is rarely diagnosed in its early stages; most of the patients are treated for strictures of the urethra, and not until late in the course is the proper label affixed and adequate treatment begun. Robb expressed the belief that it would be true wisdom immediately to suspect every pathologic change toward the formation of tumor in the urethra as tending toward malignant disease and to treat it as such.

The symptoms of the disease may be divided into three stages. In the first stage, as in stricture, there is difficulty in urination because of the early obstruction by the tumor, a difficulty that is usually accompanied by urethral pain. Often there is a purulent or blood-stained

discharge. Retention of urine sooner or later occurs, and the picture immediately suggests simple stricture. The patient looks well but as a rule feels weak. This stage may exist for several months. In the second stage, a local tumor forms. In the third stage, infection is the predominating factor; periurethral abscess forms which, on bursting, results in fistula. In 80 per cent of the cases this fistula opens on the under surface of the penis.

Peters⁴⁷ stated that primary carcinoma of the male urethra is rarely encountered; there are less than 100 cases reported in the literature. Gonorrhea, stricture, leukoplakia or any other chronic inflammatory process is probably not of primary importance.

A case is reported of a patient, aged 42. The bladder was distended, and attempted catheterization met obstruction in the deep urethra. On incision, pus and urine were encountered in the tissues. The inflammatory portion seemed to be on the edges of a distinct mass of hard tissue which had not broken down, and sections taken for examination revealed epidermoid carcinoma.

Chute, in discussing Peters' paper, reported a case in which he made an opening into the urethra and curetted a cavity behind a urethral stricture. Fifteen years later, a mass in the left side of the perineum and a fistula near the penoscrotal angle were found. Some time later, Chute operated and removed a mass of hard tissue and a considerable portion of the left side of the urethra. Microscopic examination revealed carcinoma. A year later the patient returned, showing an area of recurrence entirely surrounding the urethra. Chute cut out a section of the urethra and sewed the ends together.

[COMPILER'S NOTE: Primary tumor of the urethra is extremely rare. In one series of 16,637 cases of tumors of various organs cited by Englisch,⁴⁸ no instance of malignant growth of the urethra was noted. In another series of 4,000 cases of disease of the male urinary organs, only 3 were of carcinoma of the urethra. In 358 cases of carcinoma of traumatic origin reviewed by Lowenthal,⁴⁹ there were 2 of carcinoma of the urethra.

Occasionally urethral carcinomas are preceded, as in Chute's case, by periods of urinary difficulty and irritation. The formation of tumor is somewhat analogous to the long-standing premalignant stages preceding the development of squamous cell tumors of the urinary bladder.

König⁵⁰ reported a case of urethral carcinoma developing after urinary obstruction of forty-eight years' duration, and Oberlander⁵¹ noted a somewhat similar case developing after forty years of urinary difficulty.

The onset may be quite rapid in young persons. Barney⁵² and Fuller⁵³ both reported cases of sudden onset with acute retention. Schustler⁵⁴ reported a case of acute retention with fourteen days of uremia, followed by death. Most of these tumors occur at the usual site of the formation of the stricture. Of forty-two cases of carcinoma of the male urethra noted by Preiswerk,⁵⁵ thirty-eight were in the membranous or cavernous urethra.

Most of these carcinomas have a histologic structure similar to that of squamous cell epithelioma of the penis, although of a higher degree of malignancy. Metastatic growths, which are not common, have the same tendency to remain localized in the primary glands as do those arising from epitheliomas of the penis. At times the only symptoms are those resulting from moderate obstruction, together with marked hematuria, especially after urethral manipulation.

Diverticula.—Mouat⁵⁶ stated that urethral diverticula may be congenital or they may be acquired. Those in the prostatic urethra are most commonly acquired from the gradual increase in size and communication with the urethra of a sac containing prostatic calculi. In a less common type, the prostatic urethra may gradually become distended to form a sac as a result of the lodgment of stones in that portion of the canal. Mouat reported a number of interesting cases. In one a 2 ounce (56.7 Gm.) stone was found in a sac which communicated with the posterior urethra. At operation, the stone was cut down on from the perineum. It was deeply grooved on the surface, corresponding to the gap in the floor of the urethra. The pouch was excised, and the edges of the urethral opening were stitched together over a catheter inserted into the bladder.

In the anterior urethra, the acquired type of diverticula is much more common than the congenital variety. A case is described of a stone

56. Mouat, T. B.: Urethral Diverticula, Brit. J. Surg. 16:51, 1928.

in a pouch which communicated with the floor of the urethra at the penoscrotal juncture. The stone was cut down on, under local anesthesia, and removed from the thin-walled sac, which was tightly stretched over it. A small opening which communicated with the urethra was stitched up, and the thin-walled sac was obliterated.

In forty cases of acquired diverticula of the urethra, there was a history of a previous operation on the urethra in sixteen; in the remainder, false passages, blows or falls on the perineum and peri-urethral abscesses are stated as possible causes of the condition.

The diagnosis of a pouch opening into the anterior urethra is as a rule easily made, as the stones which are usually contained in the sac can generally be felt in the perineum. When the sac is not fully occupied by calculi, it may become distended during the act of micturition. The diagnosis is more difficult if the diverticulum is connected with the posterior urethra, although with present day urologic technic it is possible to fill the pouch with a substance that will cast a shadow and which readily outlines the diverticulum.

Calculi in the prostate gland give rise to a sense of weight, pain and irritation in the perineum and sometimes to retention of urine. Crepitation, which may be felt by the examining finger in contact with stones in a pouch, is characteristic and has been compared to "beads in a bag."

When it is possible, an attempt should be made to dissect out the wall of the sac, after it has opened and emptied of its contents. The aperture of communication with the urethra may be closed by suturing lateral flaps, which have been dissected up at the neck of the sac. Usually the most that can be done in the acquired forms of prostatic diverticula is to cut down and evacuate their contents by a median perineal section, a procedure that is sometimes followed by a reformation of stones.

McKay and Colston⁵⁷ found that reported cases of diverticula of the urethra are rare and that in only a few are methods of treatment given. The symptoms of urethral diverticula depend on the site, size, depth and degree of infection. The most obvious symptoms are deep-seated pain in the perineum, dysuria and dribbling at the end of urination. A diverticulum of the anterior urethra often presents a fluctuating tumor that fills during the act of urination and is easily emptied by pressure. A diagnosis is usually made by means of the cysto-urethroscope and the roentgen rays, and the transitory subsiding tumor is occasionally seen.

57. McKay, R. W., and Colston, J. A. C.: Diverticula of the Male Urethra, *Surg. Gynec. Obst.* 48:51, 1929.

If the diverticulum is to be resected, an incision is made over the diverticulum through the skin and subcutaneous tissues. It is then freed by sharp and blunt dissection. It is resected close to its entrance into the urethra, and its stump is turned into the urethra by a purse-string suture, similar to the manner in which the stump of the vermiform appendix is turned in. The purse-string suture is reinforced by bringing the surrounding tissues over by means of mattress sutures. The bladder is drained by an inlying catheter through the urethra; the operative area is not drained, but skin and subcutaneous tissues are closed by fine silk or silver clips.

Another operative procedure described by McKay and Colston is opening the diverticulum into the prostatic urethra, thus making one cavity. This method is applicable only to the diverticula found in the posterior or prostatic urethra. A perineal or suprapubic approach is used with the idea of removing the roof from the diverticulum and converting the cavity of the diverticulum and the cavity of the prostatic urethra into one common opening. This insures proper drainage and also obviates obstruction to urination.

In ten reported cases, seven patients were treated by operative procedures, and one was treated by the injection of silver nitrate. Two patients refused treatment. Only one case was complicated by stone. In the seven cases in which operation was performed, complete resection was done in five, followed by closure of the defect in the urethra over a soft rubber catheter. In four of five patients treated by resection, the diverticula occurred in the anterior urethra, and in one, in the posterior urethra just behind the external sphincter.

Epispadias.—Davis⁵⁸ observed that success has been attained in practically every case in which the surgical procedures in the treatment of epispadias in the female have been properly planned and executed. He stated the belief that it is unnecessary to subject the patient to the risk of ascending renal infection, which is always present after this operation.

Davis employed a two-stage procedure, the second step of which is usually not necessary when the first one is properly carried out. The first stage consists of thoroughgoing plastic repair of the defect. He made a wide exposure of the affected areas, and sufficient and thoroughly controlled excision of excessive mucosa was done under vision. It is important to cut the urethra small enough; if it is too small it can easily be dilated, but if it is too large the operation is a failure and must be repeated. Care should be used in suturing the halves of

⁵⁸ Davis, D. M.: *Epispadias in Females and Its Surgical Treatment*, J. Urol. 20:673, 1928.

the defective internal sphincter muscle over the anterior aspect of the newly formed vesical orifice. The urine should be diverted by a drainage tube in the bladder during the period of healing. If the first step should fail, Deming's gracilis muscle plastic operation is performed. Davis expressed the belief that these methods can be relied on to produce a cure in practically every case of epispadias in the female.

MALIGNANT DISEASE OF THE URINARY TRACT

Barney⁵⁹ stated that hematuria is the most common and often the earliest symptom of malignant disease of the urinary tract. It may be microscopic or macroscopic. It cannot be influenced by medication, and it may not reappear for weeks or months. Pain is not an outstanding feature of malignant disease in this region. It occurs generally at a late stage in the disease and is frequently felt in places other than the primary source. Metastasis from prostatic carcinoma occurs early and often, from the kidney later and less frequently and from the bladder, late and seldom. About one fifth of all cases of prostatic obstruction are associated with carcinoma of the prostate gland. It may not give rise to urinary symptoms.

Early diagnosis of malignant disease of the urinary tract is made with disappointing infrequency, because of the fact that it does not cause outstanding symptoms until well advanced.

URINARY INFECTION

Schlack⁶⁰ reported that in cultures made from 350 specimens of urine of eighty infants, 45 per cent remained sterile. In the non-sterile group, colon bacilli were found in one-third and cocci in the remaining two-thirds. In spite of the finding of bacteria, there was no pyuria. The pyuria may begin with bacteriuria or with symptoms of nephritis.

Experimental and clinical observations on the dehydration types of pyuria are noted but not considered as true infection. They are recognized as renal symptoms, since there are no bacteria present and the cells in the urine are mainly mononuclears, which Schlack assumed came from the renal tubules. In many cases, in spite of early pyuria, the sediment contains mostly mononuclears. Doubtless these cells in the urine are epithelial in origin. Microscopic study of the kidney supports this view.

EXTRAVASATION OF URINE

Soloway⁶¹ stated that extravasation of urine is an emergency condition demanding immediate surgical attention. It is caused by stricture of the urethra in most cases and is usually accompanied by a periurethral abscess. In cases of extravasation in which there is no obstruction to urinary outflow, the anaerobic organisms are significant etiologically. The course of the extravasated urine is determined by the relationship between the point of rupture of the urethra and the fascial planes of the perineum. The most common site of rupture is the bulbous urethra, then the membranous urethra, and rarely the prostatic urethra. The physical state of the urine at the time of rupture was observed to play an important part in the course of the condition. Soloway expressed the belief that the best results are obtained by radically opening the focus of infiltration with wide incisions and by rectifying the stricture, when present. Both of these procedures should be done at the same time. Spinal anesthesia has given satisfactory results.

Streptococcus scrotal and penile gangrene and idiopathic gangrene of the scrotum are conditions which closely resemble extravasation and from which it must be distinguished. The prognosis depends on early diagnosis, the duration of the extravasated urine, and immediate radical operation.

URINARY ANTISEPTICS

Voit⁶² conducted experiments to determine whether or not the body disposes of methenamine mainly through the urinary tract or by other means. He found that in the oral administration of methenamine (from 2 to 200 Gm.) free formaldehyde is formed within fifteen minutes; in hyperacidity, it occurs in correspondingly greater amounts. It is to be assumed that this formaldehyde may be lost as far as therapeutic value is concerned, as it is not always found in the urine. Methenamine administered intravenously yields greater quantities and for that reason is found more often in the urine as free formaldehyde.

Further research and animal experimentation have shown that it is excreted by the liver. Voit also showed that it may be excreted by the skin. From these data he concluded that if any therapeutic value is to be obtained by its administration by mouth, large quantities must be given.

FUNCTIONAL TESTS

Bugbee⁶³ stated that renal function is one of the most vital factors influencing the treatment for urologic surgical conditions. Subsequent

⁶³ Bugbee, H. G.: The Role of Kidney Function in Urologic Surgery, *J. Urol.* **20**:541, 1928.

to operation, a continuous knowledge of renal function is of decided value in checking off the progress, estimating the prognosis and influencing the future conduct of the case. Such knowledge is particularly applicable in cases of prostatic obstruction, in which, due to back pressure on the kidneys, congestion soon gives way to renal injury. Dating from the time when regional anesthesia was adopted as a routine measure, in a series of 171 consecutive cases of prostatic obstruction in which treatment was by open operation, only 1 patient (the one hundred and twenty-seventh) died.

Combined estimations of the chemical constituents of the blood and phenolsulphonphthalein have been found satisfactory in determining renal function, but the limitations of either when employed alone have been demonstrated. The observation of a persistently high blood urea has indicated poor renal function. Under reduced protein diet and forced fluids it has been observed that the blood urea often recedes rapidly, while the phenolsulphonphthalein output remains low. In these cases estimations of blood urea alone are of little value, or in combination with the phenolsulphonphthalein test should not influence one against the evidence produced by the phenolsulphonphthalein elimination.

Bugbee attempted to maintain as closely as possible a renal balance throughout. Necessary preliminaries to this end are slow decompression of the bladder, should the residual average be more than 300 cc., and drainage with the indwelling catheter until the function has been stabilized under the relief of back pressure. Bugbee expressed the belief that the type of procedure used in cases of benign hypertrophy of the prostate gland is mainly a matter of personal choice for the operator to decide in the particular case. In his series, if there was the slightest doubt as to the advisability of preliminary cystostomy, this procedure was instituted. In 5 of the 171 cases perineal prostatectomy was done, and in 5, suprapubic prostatectomy in one stage. In 2 cases of carcinoma, only permanent suprapubic drainage was established. In 8 cases a punch operation was adequate after preliminary cystostomy, the prostate gland having become reduced to such an extent that only a fibrous ring remained. Enucleation through a drainage wound is seldom difficult; in none of Bugbee's series was enucleation incomplete or tabs left to interfere with function. There is less tendency to hemorrhage following enucleation after cystostomy drainage, and it is more easily controlled with the hemostatic bag than after the single operation.

Only 4 operative deaths occurred in 181 consecutive operations on the kidney. With due credit to the significance of the early and correct diagnosis of renal lesions, Bugbee considered that a higher mortality was prevented by continued study of the affected kidneys, which largely governed the management of the cases.

TESTS OF RENAL FUNCTION

Maxwell⁶⁴ referred to a study made by MacAdam and Shiskin who found that the cholesterol content of the plasma appears to be a fair measure of the degree of the individual resistance to infection. Such estimations form a useful guide to the degree of operative risk in cases of urinary obstruction. Assuming the lower limit of the plasma cholesterol in health to be 0.13 Gm. per hundred cubic centimeters, they found that of eighteen patients with values below this limit, sixteen died of pyelonephritis and only two recovered. Of the seventy patients with cholesterol values above 0.13 Gm. per hundred cubic centimeters, eleven died, in only one of whom was death a result of ascending urinary infection. It was also noted that, in a large proportion of the cases in which low cholesterol value was found, the clinical condition did not contraindicate operation, and such clinical evidence as there was depended on some degree of defect in renal function rather than on the latent sepsis, from the effects of which the patients ultimately succumbed. MacAdam and Shiskin considered that the test is of much less value in cases of malignant disease, the cholesterol figure being frequently high even when pyelonephritis coexists. Maxwell pointed out that there is a wide variation in the cholesterol content of presumably normal blood figures, varying from 0.08 to 0.23 per hundred cubic centimeters. In this respect it must be clearly recognized that the interpretation of the results of determination of plasma cholesterol differs considerably from that of the other common chemical examinations of the blood. The blood urea and blood sugar have much less variable normal values, and neither is so liable to be affected by a multitude of external factors, partly recognized but still partly unknown, as is the plasma cholesterol. Of five patients with low cholesterol values and who should have been bad risks, two died and three recovered; whereas, of twelve patients with normal cholesterol values, four were clinically unfit for any operation. Three of the remaining eight patients died. Maxwell stated that these results do not bear out the claims of MacAdam and Shiskin as to the significance of the plasma cholesterol from a prognostic point of view.

The chief difficulties in the interpretation of the results appear to be the wide range of variation which may be observed in normal persons and the consequent impossibility of gaging the level in health for any given case. Acute retention of urine appears to have considerably more effect in lowering the plasma cholesterol content than is realized at present, so that deductions should not be drawn from results obtained only previous to the relief of the obstruction.

⁶⁴ Maxwell, James: The Significance of the Blood-Cholesterol in Genito-Urinary Surgery. *Brit. J. Surg.* 16:226, 1928.

The impression gained was that clinical observation, combined with observations on blood urea and urea concentration, yielded in most cases a reasonably accurate forecast of future events. On several occasions a low plasma cholesterol content suggested a bad prognosis, which did not materialize, whereas other patients with normal cholesterol values but who were bad operative risks clinically were either refused operation on clinical grounds alone or died shortly thereafter as a result of some complicating infection.

It would seem that owing to the present rudimentary state of knowledge concerning the cholesterol content of the blood plasma, it is impossible to achieve an accurate summing up, with consequent enlightenment, from the consideration of any individual case. Maxwell expressed the belief that what is really needed is a more intensive study of the normal values obtained in healthy persons, a more complete investigation of the factors causing changes in the plasma cholesterol, and a closer study of cholesterol values and of cholesterol curves in different pathologic states. It would be unjust to refuse operative assistance to any patient suffering from the effects of urinary obstruction merely because on one occasion previous to the proposed operation a low plasma cholesterol value had been reported. Such results are extremely likely to be equivocal, and interpretation is open to fallacy.

TRAUMATIC SUBCLAVIAN ARTERIOVENOUS ANEURYSM

FINAL REPORT *

EDGAR LORRINGTON GILCREEST, M.D.

SAN FRANCISCO

It is interesting that a condition for which the treatment is purely surgical should have fascinated one of the world's greatest clinicians, who contributed much to the history and to the present scientific knowledge of arteriovenous aneurysm. No physician or surgeon can fail to be thrilled by reading the contributions of Sir William Osler on this subject. Immediately one is impressed with the true catholicity of the pure scientific mind which he possessed. He himself stated: "Better than any other disease, aneurysm illustrates how borderless are the boundaries of medicine and surgery." There is a wealth of meaning to be gleaned in this one sentence in this day of necessary specialization which frequently leads, unfortunately, to a contracted point of view of disease as a whole.

A study of medical history reveals that the aneurysm has had a particular fascination for many of the greatest masters in medicine. The names which come immediately to mind are Rufus of Ephesus and Antyllus in the second century and, later, William and John Hunter. William Hunter, in 1757, was the first to recognize and to describe the symptoms of arteriovenous aneurysm. John Hunter, a few years later, was the first to operate, and successfully, on a patient with this condition. In the present day, William Halsted and Rudolph Matas have added valuable contributions. Although 1,800 years have rolled by, and indeed, much knowledge, bit by bit, has been acquired, surgeons are still searching for additional information in order to explain definitely and finally two questions in physiology: (1) the exact mechanism of the enlargement of the heart, and (2) the retardation of the pulse rate on closure of the arteriovenous fistula.

The answer to this question of the treatment is likewise sought: whether the ligation of the accompanying vein is imperative in an arteriovenous fistula or at least advisable in a simple aneurysm, unless

* Submitted for publication, March 29, 1929.

circumstances permit restoration of the original channels with elimination of the fistula after the method of Matas.

From the point of view of treatment, aneurysms resolve themselves into two types: (1) that in which the artery alone is involved, known as a simple, saccular or fusiform aneurysm, and (2) that in which the artery and vein are both involved and a communication is thereby established between them, known as an arteriovenous fistula or aneurysm. In the latter condition there is more involvement of the venous system, and it is this lesion only with which I am at present concerned. It is most important in the treatment to know definitely which of the two conditions is present.

The multiplicity of the names for this second group of lesions is often misleading. 1. By arteriovenous aneurysm or varicose aneurysm is meant an indirect communication between an artery and a vein by an intermediary sac or channel. 2. By arteriovenous fistula or aneurysmal varix is meant a direct communication or immediate apposition between an artery and a vein.

The report of the present case is of particular interest because of (1) the duration of the arteriovenous aneurysm; (2) the development of the right side of the chest, the right shoulder girdle and the entire upper right extremity to tremendous size, and (3) data collected before and after operation which add important proof to many of the experimental and clinical observations and the studies of Halsted, Matas, Reid and Holman.

The combination of ligations executed in this case, as far as I can ascertain, has never been used before. James E. Thompson, in 1915, ligated the innominate artery successfully for the cure of a subclavian aneurysm in its first portion. He was able to find authentic references to fifty-two similar ligations in which there were sixteen recoveries, that is, 30.7 per cent. Since 1880, the procedure has been followed twenty-six times, with twelve recoveries and fourteen deaths. As Thompson stated, "This death roll, 53.8 per cent, is enormous, but the disease, is almost certainly fatal sooner or later unless treated by surgical means."

A preliminary report of this case was made on Dec. 8, 1927, before the Western Surgical Association in Omaha. At that time, the patient was clinically well. He has since returned to the hospital and additional distal ligations have been successfully accomplished, with the result that all evidence of the aneurysm has disappeared, his arm has decreased to normal size and he "feels perfectly well." I therefore desire to review the case in full and make a final report.

REPORT OF CASE

A Mexican, aged 35, had been married for seven years and had five children. His wife had had no miscarriages. The patient stated that he had always been

well and strong, and that he did not smoke or drink alcoholic beverages. The only accident which he had ever sustained was the following:

On Dec. 12, 1920, while walking down the street in Navojoa, Mexico, about 11 p. m., on the way to his hotel, he was halted by two bandits who were crouched on the ground; the instant that he was ordered to hold up his hands he was shot through the chest. The bandits were in front and somewhat to his left. This gave the bullet an upward and outward direction. Immediately he became unconscious and fell to the ground. After three hours he awoke and found himself in a pool of blood. He gradually made his way to the hotel, about 500 yards distant, resting at frequent intervals. On his arrival there a physician was secured at once.

The wounds were healed in fifteen days. The patient remained in bed about twenty-five days. On the second day after the injury he felt a thrill beneath the right clavicle. The arm was paralyzed and numb immediately after the accident and remained so for four or five weeks. Then there began to be terrific pains and cramps in the entire arm; these gradually lessened. Two or three weeks later the patient was able to move his arm. From the day of injury the arm was swollen and darker than normal. The patient was told by the physician that he had an aneurysm and that he needed an immediate operation. The patient hesitated to have it performed at that time as he desired further consultation.

About Jan. 20, 1921, he returned to his work as bookkeeper. He did not attempt to use his right arm as it was "weak and stiff." He was at this time under no physician's care, and the arm hung limp at his side. He rubbed it frequently to stimulate the circulation. By July, six months after the injury, the pain had subsided a great deal, much strength had returned and there was much better movement of the fingers. The patient now began to work with his right arm and hand. He wrote with it, did bookkeeping and drove an automobile, but he could not use a typewriter or lift any weight. During this time the diseased arm was only slightly larger than the other.

In September, 1921, the patient sought the opinion of a surgeon in Mexico City on account of the increased distention of the veins over the axillary fold and chest. An operation was not advised, and the patient returned home.

From this time until eight months before the first operation, there was little change except that the arm slowly increased in size, and the veins in the axilla and over the anterior part of the chest became more and more distended. During these seven years the patient carried on his regular work about the office and was able to do almost everything except use a typewriter, which was prevented by lack of mobility of the fingers.

About April, 1927, the patient noticed that his entire arm was becoming much larger and heavier, and that he was unable to use it as before. The veins in the upper part of the arm, axilla and chest became more visibly distended. After that time he noticed that if he put his hand down it immediately became much swollen. Also during 1927, he began to have shortness of breath even when standing still in the office. This dyspnea was distressing when he attempted to walk fast or ascend stairs. He found it impossible to run or climb stairs rapidly. He stayed within his reserve and therefore was not compelled to sit down to rest frequently. He never fainted. His sleep was sound and restful. At no time did he have symptoms in the head or notice any swelling of the ankles.

During the six weeks before operation the arm increased more rapidly in size than before. In fact, it became so huge that he found it impossible to insert it in the sleeve of his coat. The arm felt very heavy. The swelling in the region of the elbow made it impossible for him to bend it very much. The swelling in

circumstances permit restoration of the original channels with elimination of the fistula after the method of Matas.

From the point of view of treatment, aneurysms resolve themselves into two types: (1) that in which the artery alone is involved, known as a simple, saccular or fusiform aneurysm, and (2) that in which the artery and vein are both involved and a communication is thereby established between them, known as an arteriovenous fistula or aneurysm. In the latter condition there is more involvement of the venous system, and it is this lesion only with which I am at present concerned. It is most important in the treatment to know definitely which of the two conditions is present.

The multiplicity of the names for this second group of lesions is often misleading. 1. By arteriovenous aneurysm or varicose aneurysm is meant an indirect communication between an artery and a vein by an intermediary sac or channel. 2. By arteriovenous fistula or aneurysmal varix is meant a direct communication or immediate apposition between an artery and a vein.

The report of the present case is of particular interest because of (1) the duration of the arteriovenous aneurysm; (2) the development of the right side of the chest, the right shoulder girdle and the entire upper right extremity to tremendous size, and (3) data collected before and after operation which add important proof to many of the experimental and clinical observations and the studies of Halsted, Matas, Reid and Holman.

The bandits were in front and somewhat to his left. This gave the bullet an upward and outward direction. Immediately he became unconscious and fell to the ground. After three hours he awoke and found himself in a pool of blood. He gradually made his way to the hotel, about 500 yards distant, resting at frequent intervals. On his arrival there a physician was secured at once.

The wounds were healed in fifteen days. The patient remained in bed about twenty-five days. On the second day after the injury he felt a thrill beneath the right clavicle. The arm was paralyzed and numb immediately after the accident and remained so for four or five weeks. Then there began to be terrific pains and cramps in the entire arm; these gradually lessened. Two or three weeks later the patient was able to move his arm. From the day of injury the arm was swollen and darker than normal. The patient was told by the physician that he had an aneurysm and that he needed an immediate operation. The patient hesitated to have it performed at that time as he desired further consultation.

About Jan. 20, 1921, he returned to his work as bookkeeper. He did not attempt to use his right arm as it was "weak and stiff." He was at this time under no physician's care, and the arm hung limp at his side. He rubbed it frequently to stimulate the circulation. By July, six months after the injury, the pain had subsided a great deal, much strength had returned and there was much better movement of the fingers. The patient now began to work with his right arm and hand. He wrote with it, did bookkeeping and drove an automobile, but he could not use a typewriter or lift any weight. During this time the diseased arm was only slightly larger than the other.

In September, 1921, the patient sought the opinion of a surgeon in Mexico City on account of the increased distention of the veins over the axillary fold and chest. An operation was not advised, and the patient returned home.

From this time until eight months before the first operation, there was little change except that the arm slowly increased in size, and the veins in the axilla and over the anterior part of the chest became more and more distended. During these seven years the patient carried on his regular work about the office and was able to do almost everything except use a typewriter, which was prevented by lack of mobility of the fingers.

About April, 1927, the patient noticed that his entire arm was becoming much larger and heavier, and that he was unable to use it as before. The veins in the upper part of the arm, axilla and chest became more visibly distended. After that time he noticed that if he put his hand down it immediately became much swollen. Also during 1927, he began to have shortness of breath even when standing still in the office. This dyspnea was distressing when he attempted to walk fast or ascend stairs. He found it impossible to run or climb stairs rapidly. He stayed within his reserve and therefore was not compelled to sit down to rest frequently. He never fainted. His sleep was sound and restful. At no time did he have symptoms in the head or notice any swelling of the ankles.

During the six weeks before operation the arm increased more rapidly in size than before. In fact, it became so huge that he found it impossible to insert it in the sleeve of his coat. The arm felt very heavy. The swelling in the region of the elbow made it impossible for him to bend it very much. The swelling in

the hand and fingers prevented any work with the hand. About six weeks before operation the patient also developed two ulcers, one on the dorsum of his hand and the other on the flexor surface of his forearm; these increased in size. As his entire upper right extremity and shoulder had become useless and a burden his physician in Mexico advised him to go to San Francisco and have a shoulder

Fig 1 (Sept. 15, 1927)—Traumatic subclavian arteriovenous aneurysm, six weeks before the first operation. Note the great swelling of the upper arm.

girdle amputation. He reconciled himself to this as inevitable and came to me for the operation, being referred by Dr. Frederick Kroll of San Francisco.

It is interesting that during the preceding seven and one-half years no one suggested elevation of the arm or a pressure bandage to relieve the chronic passive congestion with resulting edematous infiltration. During all this time the valves in the veins were gradually giving away.

Examination.—The patient was a remarkably well developed and well nourished man with an extremely broad chest. There was the scar of a bullet wound of entrance over the third costochondral junction to the right, 6 cm. from the middle of the manubrium, and the corresponding scar of a bullet wound of exit over the posterior aspect of the supraclavicular region, 5 cm. from the neck, and just posterior to the lateral edge of the trapezius muscle; the tract apparently traversed the structures underneath the clavicle at its midportion. There was a tremendous swelling, involving the entire right side of the chest wall (fig. 3) including the breast, the right nipple, which was about 3 cm. lower than the left, the pectoral region, the axillary region, and the entire shoulder girdle, arm, forearm and hand (fig. 4). There were large tumor masses, the size of a grapefruit, consisting of huge dilated veins the size of a finger; these were especially visible in the pectoral and axillary region, in the upper third of the arm and along its flexor surface. Although the patient's skin was naturally dark, it was readily seen that the right hand and arm were several shades darker than the left. This darkening of the skin was conspicuous enough to attract the patient's own attention to it. There were two large, indolent, varicose ulcers about 5 by 7 cm. in diameter on the dorsum of the hand and the flexor surface of the forearm.

Fig. 2.—Six weeks before the first operation. Note the patient's inability to extend the arm fully.

A systolic thrill was distinctly palpable in the supraclavicular region, less distinctly palpable in the infraclavicular region and distinctly palpable in the axillary region and over the lower third of the inner aspect of the upper arm where the basilic vein courses. Here it was like the purring of a cat.

On auscultation over the right supraclavicular region a continuous booming sound was audible, with systolic accentuation. This bruit was distinctly audible but decreased over the right side of the chest. It was again heard distinctly in the axillary region where it sounded like the murmur of machinery. In fact, the sound was similar to the roar one hears in a subway when a train whirls past. Over the lower third of the arm, where the thrill was most palpable, a loud bruit could be heard with systolic intensification. Here the sound was of a much higher pitch and reminded one of the whistling of the wind. This sound was even transmitted to the upper third of the forearm.

Deep digital pressure applied just above the center of the right clavicle made the thrill imperceptible and the bruit inaudible. On release of the pressure, they instantaneously returned. Presumably this pressure completely obliterated the communication between the subclavian artery and vein. It also produced an

immediate elevation in both diastolic and systolic blood pressure, which rose in the left arm from 134 to 154 systolic and from 74 to 94 diastolic; and a retardation of the pulse from 84 to 76, Branham's bradycardiac reaction. Matas stated: "This is by far the most important and early sign of the cardiovascular disturbances brought about by an arteriovenous fistula and is of great diagnostic significance in all cases in which the arteriovenous connection is accessible to compression." The right radial pulse could be palpated with difficulty. The hand felt cold.

There were no disturbances of motion or sensation in the right arm, with the exception that the great swelling made it impossible for the patient to extend his arm or to flex his fingers completely.

Fig. 3.—Six weeks before the first operation. Note the large lakes of dilated veins over the right side of the chest.

Between the right thumb and index finger the temperature was 35.7 C. and between the left thumb and index finger it was 36.2 C. Examination of the blood showed: hemoglobin, 90 per cent; erythrocytes, 4,800,000; leukocytes, 6,150. The differential count showed: polymorphonuclears, 69 per cent; lymphocytes, 25 per cent; eosinophils, 2 per cent and transitionals 4. The Wassermann test was 4 plus. The urine showed a slight trace of albumin and an occasional hyaline cast.

Blood from a vein of the right arm gave an oxygen content of 11.4 per cent by volume and from the left arm 69 per cent by volume; blood from a vein of the right arm gave a carbon dioxide content of 38 per cent by volume, and from the left arm 49.4 per cent by volume.

On Nov. 3, 1927, a 6 foot (1.8 meters) ventral projection showed the heart definitely increased above normal size. The enlargement seemed to affect the left ventricle predominantly. The aorta was neither elongated nor dilated. The right side of the chest was a little less well expanded than the left in its upper portion.

Diagnosis.—The lesion was diagnosed as an arteriovenous aneurysm of the subclavian artery and vein, rather than a simple aneurysm. This conclusion was based on the following factors: (1) the great swelling of the arm, (2) the great dilatation of the veins, (3) the continuous purring thrill, (4) the continuous buzzing or machinery-like murmur accentuated during systole, (5) the centrifugal

Fig. 4.—Six weeks before the first operation. Note the great swelling also of the forearm and hand.

Fig. 5 (Nov. 4, 1927).—One day before the first operation. Note the decrease in swelling after six weeks of elevation and the application of an elastic bandage.

transmission of the bruit and thrill along the course of the axillary and basilic veins, (6) the elevation of blood pressure on temporary deep pressure over the site of the lesion, (7) the retardation of the pulse on temporary deep pressure over the site of the lesion, (8) the increase of oxygen content in the veins of the right arm, (9) the decrease in local temperature and (10) the enlargement of the heart.

For several weeks prior to the operation the patient was kept in bed; his right arm was elevated in a Thomas splint and crepe bandages were applied to the entire arm and shoulder girdle. This proved effectual in decreasing a great deal of the edema. It also afforded the heart a necessary rest (fig. 5).

The plan of operation consisted of the following steps: (1) subperiosteal resection of the proximal two thirds of the clavicle, (2) transection of the muscles of the neck, permitting thereby: (3) the free exposure of the great vessels of the upper part of the chest and neck, (4) possible ligation of the innominate artery and vein and the carotid artery and jugular vein, (5) or ligation of the subclavian artery and vein; and (6) further, if practicable, ligation of the artery and vein distal to, and as close to, the sac as possible, but proximal to the origin of the posterior circumflex and subscapular vessels—in short, a quadruple ligation of the fistula or aneurysm.

This procedure was carried out twice on a cadaver previous to the operation.

The operation was performed on Nov. 5, 1927, at 9:30 a. m. Forty-five minutes before the operation, the patient was given a hypodermic injection of $\frac{1}{4}$ grain (16 mg.) of morphine and $\frac{1}{150}$ grain (0.4 mg.) of atropine. He was placed on the table with shoulders and head slightly elevated; the head was slightly extended and turned to the left side. Local anesthesia of 0.5 per cent procaine hydrochloride was given. This was first injected near the angle of the jaw and just under the chin in the midline in order to apply the towel skin clips without hurting the patient. Starting at a point between the articulation of the clavicle to the manubrium, procaine hydrochloride was injected 3 cm. to the left and over the right clavicle to its outer third and from the manubrium up along the anterior border of the sternomastoid muscle for 7 cm. An incision was now made from the outer third of the right clavicle and slightly below it, and extended up along the anterior border of the right sternomastoid muscle for 8 cm. The skin flap was dissected in both directions. The sternomastoid muscle was divided. The triangular flap of skin and muscle was turned upward and outward. The external jugular vein was ligated.

The sternohyoid and sternothyroid muscles were severed about 1.5 cm. above the sternum and laid back. A subperiosteal resection of the inner two thirds of the clavicle was carried out; it was cut through with a Gigli saw and disarticulated at the sternum. With this exposure the large mass of dilated veins under the clavicle and over the arteriovenous aneurysm, as well as the large vessels of the neck, came clearly into view (fig. 6). The arteriovenous aneurysm involved the second and third portions of the subclavian artery and vein. It should be recalled that the subclavian artery and vein are not companionate in their first part but are separated by the anterior scalene muscle. The mass of large veins over the aneurysm were adherent to each other and to all the surrounding tissues. One of the larger veins, thought to be the subclavian, was ligated at its outer third, as a thrill could be felt over the proximal area.

Gas and ether were administered at 10:30 a. m. The carotid artery was located with the adjacent vagus nerve and dissected down along the anterior and inner surface until the subclavian artery could be felt coming up from behind and bifurcating with it at an acute angle. The subclavian artery was then followed up. It was seen to be enlarged and to emerge into the aneurysm in its second portion. The subclavian vein in nearly its entirety was part of the aneurysm, the remaining proximal end being greatly dilated. For this reason it was decided to ligate the innominate vein. Then the internal jugular was ligated, medium braided silk being used for the ligations. In attempting to push the pleura downward and outward in order to free the subclavian artery, a slight tear occurred in it producing a slight pneumothorax. Contrary to the observation of most authors, the first portion of the subclavian artery was not found difficult to ligate. Heavy braided silk was used and a double ligation was performed after the method of Ballance and Edmunds. With the exposure obtained, one could dis-

tinctly see the best site for the ligation and could feel sure that the recurrent laryngeal nerve was not incorporated in the ligature.

No thrill could be felt now, but as there was still some dilation of the veins over the aneurysmal varix, one of the large veins toward the distal portion was ligated. In attempting to free this large vessel with its thin wall from the adherent tissue and veins, and to pass the aneurysm needle around it some venous hemorrhage occurred which was fairly easily controlled. The mass immediately became smaller with the ligation of this vessel, which was thought to be the subclavian vein. In all, I ligated the innominate vein, the external jugular and the internal

Fig. 6.—Great mass of dilated veins beneath the clavicle. The aneurysm is between the subclavian artery and vein.

jugular veins, the subclavian vein in two places and the subclavian artery in its first portion (fig. 7).

The question that naturally presented itself then was whether to attempt further dissection through this veritable wilderness of matted dilated thin-walled veins and to execute a distal ligation of the artery and vein, that is, the third part of the subclavian artery and vein or the axillary artery and vein with a possibility of dissecting out completely the aneurysmal sac, or to rest on the laurels won. As the procedure had already consumed more than three hours and as no thrill could now be felt nor bruit heard, it was decided to adopt the latter course, in the hope that with the aid of these ligations nature might close the fistula, if any

remained. The severed muscles were brought in apposition and sutured, and the wound was sutured in layers without drainage.

Postoperative Progress.—The patient manifested practically no evidence of shock. The wound healed per primam. Some swelling in the right supraclavicular space was observed on the sixth day, when the stitches were removed. This was due to an accumulation of serum which was aspirated on the eighth, tenth, thirteenth and twenty-first days after the operation. The fluid did not return.

The blood pressure which previous to operation was 134 systolic and 74 diastolic was 136 systolic and 74 diastolic one hour later. The next day, it was 150 systolic

Fig. 7.—Sites of the ligation of the external and internal jugular, subclavian and innominate veins and the subclavian artery. (From Sabota's Anatomy.)

and 112 diastolic; two days later, 152 systolic and 86 diastolic, and the third day, 164 systolic and 82 diastolic; it then gradually declined until on the twenty-eighth day it was 124 systolic and 74 diastolic.

The day following the operation, the patient complained of severe pain in the lower right anterior axillary region when an attempt was made to change his position or to move his right arm. On the tenth day the classic signs of fluid were present in the right lower portion of the chest, and a roentgenogram revealed a fluid line. A thoracentesis was performed on the fifteenth and seventeenth days, but only on the latter day were 2 ounces of sanguineous fluid aspirated. This was repeated on the twentieth day with the same success. Two days later no fluid

could be seen in the chest. The lung, which had been collapsed, due to the pneumothorax, was now expanded. The diaphragm was high and did not move, indicating that the right phrenic nerve had been injured.

A diminution in the size of the right side of the chest, the entire shoulder girdle, arm, forearm and hand was conspicuous after the second day, and continued uninterruptedly, as shown by the accompanying table of circumferential measurements (table 1). This decrease in the venous channels is of particular interest when it is remembered that the innominate, subclavian and jugular veins were ligated.

On Dec. 5, 1927, twenty-eight days after operation, the patient was feeling well. The swelling of the arm was decreasing steadily (fig. 8). The bruit was becoming less and less distinct. Only a slight thrill was palpable. The patient returned to his home in Mexico that day.

Whether in this case a quadruple ligation should have been carried out at this time, thereby subjecting the patient to considerable additional risk, deserves consideration. Time will best answer this question. While the surgeon should be daring he must never lack restraint. If I had performed this operation, there

TABLE 1.—Circumferential Measurements During the First Stage of Treatment, 1927

	Oct. 29	Oct. 25	Nov. 14	Nov. 12	Nov. 24	Dec. 5
Area	Cm.	Cm.	Cm.	Cm.	Cm.	Cm.
Wrist	19.25	18	18	17.25	17.0	16.5
Middle forearm, 14 cm. above wrist.....	32.0	29	26	25.0	25.0	24.5
Elbow	40.0	34	33	32.0	31.0	29.5
Middle arm just below greatest swelling.....	52.0	43	42	41.0	39.5	38.0
Over greatest swelling, upper third of arm...	55.0	51	49	47.0	43.5	41.0
Axilla	53.0	50	47	45.0	45.5	44.0
Around shoulder girdle, 9 cm. from nipple....	66.0	61	60	55.0	55.0	54.0
Right side of chest at level of midline.....	68.0	64	56	53.0	53.0	52.5
Left side of chest at level of midline.....	50.0	50	50	50.0	50.0	50.0

would have been no opportunity to see what nature could do in finally closing the fistula or aneurysm when partial ligation had been accomplished. As Halsted said, "Surgeons should bear always in mind the opportunities which they have daily at the operative table to strive for results which may be contributory to the advancement of their science. The operating room is a laboratory for the surgeon."

Second Admission.—On Aug. 6, 1928, the patient was readmitted to the hospital, stating that he had felt perfectly well since the first operation on Nov. 5, 1927. He had been working regularly, using both arms and hands with ease. The great swelling of his shoulder, arm and hand had not returned. Seven weeks before the second admission, however, with the advent of very warm weather, he noticed that the veins in the axilla became larger. Coincidentally, a varicose ulcer developed over the flexor surface of the right forearm. Six days before, he had awakened during the night to find that a considerable hemorrhage had occurred in this ulcer and that he was lying in a pool of blood. During the next five minutes he continued to bleed so profusely, that he thought he would die. Pressure controlled the hemorrhage, however, and he left Mexico the next day for San Francisco.

Examination.—Examination (fig. 9) at this time revealed a slight increase in the swelling of the right shoulder girdle and arm, but there was no return of the

great swelling seen prior to the first operation. The patient was able to slip his arm into his coat sleeve and he walked about with ease. The circumferential measurements are shown in table 2.

Over the flexor surface of the midportion of the forearm there was an ulcer, 3 cm. in diameter, surrounded by markedly discolored skin and an induration of the soft tissue. In fact, the entire right arm and hand were much darker than the left. No pulse could be felt at the right wrist. There was no impairment of motion or sensation at any point. The clavicle, the inner half of which was removed, showed definite regeneration.

Just above this regenerated clavicle, at its midpoint, there was still a thrill on deep palpation. This thrill could also be felt on deep palpation in the axilla over

Fig. 8 (Dec. 5, 1927).—One month after the first operation. Note the great reduction in the swelling of the right side of the chest and the entire right arm.

Fig. 9.—Note the gradual recurrence of the swelling, nine months after the first operation.

the mass of tortuous large veins which lay just underneath the skin. There was a point just above the elbow where the thrill was distinctly felt and heard on auscultation. Deep pressure above the clavicle resulted in a complete disappearance of the thrill and bruit and visible recession in the size of the dilated veins in the axilla. Before the closure of the fistula the blood pressure in the left arm was 140 systolic and 82 diastolic. On closing the fistula the blood pressure immediately rose to 158 systolic and 90 diastolic, dropping as long as the fistula was closed to 150 systolic. Accompanying this increase in blood pressure, there was a slowing of the pulse from 72 to 64. The heart sounds were normal. The apex beat could barely be felt in the nipple line. There was no increase in precordial activity and the heart was not demonstrably enlarged to percussion.

The hemoglobin was 90.5; the red cells, 4,900,000 and the white cells, 9,900. The Wassermann reaction was 3 plus.

Examination of the urine revealed a slight trace of albumin.

On Aug. 8, 1928, the right leaf of the diaphragm was still very high, the dome reaching just above the fifth rib anteriorly. It was not quite so high as on Dec. 1, 1927.

The heart was still large; it appeared appreciably larger than on Nov. 3, 1927, before the first operation. Measurement of the shadow of the heart vessel by planimeter showed that on Nov. 3, 1927, it was 189 sq. cm., and at the time of the second admission it was 198.3 sq. cm. Apparently the high diaphragm produced a torsion of the heart with a greater apparent than actual increase in size.

It was quite evident that the condition was an arteriovenous aneurysm which had reestablished itself following ligation of the subclavian artery in its first portion and ligation of the innominate, subclavian and jugular veins about eight months before.

Operation.—It was decided: (1) to resect the completely regenerated inner portion and outer third of the clavicle which was still intact; (2) to expose the axillary vessels beyond the communication between the vessels, which lay probably in the third portion of the subclavian artery; (3) to identify the structures distal to the fistula, and (4) to expose the aneurysm itself, separate the vessels, preserve the artery and vein, if possible, and if not, excise the aneurysm.

Operation was performed on Aug. 10, 1928, at 9 a. m. Gas anesthesia was used throughout the operation. The patient was placed in position with the arm at right angles to the body, and the shoulders slightly elevated. An incision was made along the line of the old scar extending laterally to the coraco-acromial articulation. The regenerated portion of the clavicle was removed as well as about 2.5 inches (6.3 cm.) of the intact clavicle. Numerous dilated veins were encountered in approaching the clavicle. Whether it was due to the position of the arm it is difficult to say, but it was almost impossible to palpate the thrill which previously had seemed quite prominent over the center of the clavicle. There was no pulsation to be felt in any of the vessels except in the common carotid artery on the right side. Identification of structure was extremely difficult, primarily because of this absence of the thrill and pulsation; the scar tissue resulting from the previous operation still further obscured the normal tissue. It was felt wise to continue the dissection down the arm in an endeavor to expose normal tissue and then work back toward the supposed location of the communication. The subclavius muscle was divided as was a considerable portion of the pectoralis major.

After some difficulty the axillary vein was finally identified. This hugely dilated vein had a diameter of 2.5 cm. On further exposure the vein was found to be pulsating; closure of it resulted in the identification of the aneurysmal sac about the size of an English walnut which lay just below and posterior to the middle of the clavicle. A faint thrill could be felt over this aneurysmal sac which was completely controlled by closure of the axillary vein beyond it. Closely adherent to this sac, just superior to the axillary vein were cords of the brachial plexus; these, in turn, surrounded the axillary artery which at this point was approximately 4 mm. in diameter. There was no pulsation to be felt in this axillary artery beyond the aneurysmal sac. This resulted in a considerable delay in its exact identification. The ligation of the axillary vein with a piece of narrow tape produced a conspicuous and easily palpable pulsation of the aneurysmal sac. An attempt was then made to find the arterial connections with this sac, but

pressure at any particular point failed to influence the pulsation greatly. The subclavian artery was identified, lying just posterior to the scalenus anticus muscle (fig. 10).

It is interesting to note that this artery was not palpable before ligation of the axillary vein, primarily because of the large venous reservoir into which it emptied. Closure of the subclavian artery just beyond its emergence from the scalenus muscle resulted in a marked diminution in pulsation, but not in the complete

Fig. 10.—Sites of ligation of the axillary and long thoracic veins, and the subclavian, axillary and long thoracic arteries. (From Deaver's Surgical Anatomy.)

control of the arterial supply of the sac. It was ligated with braided silk. The axillary artery was ligated with silk, with a little further diminution of the pulsation of the sac. The long thoracic artery and vein lying posterior to the axillary vein were also ligated with braided silk. This controlled the pulsation of the sac almost completely. It was felt, however, that with ligation of the axillary vein and almost complete control of arterial supply, the aneurysmal sac would probably be closed by thrombosis. It was thought that the subclavian

artery in its third portion emptied almost completely into this aneurysmal sac which in turn emptied into the very large axillary vein. It is worthy of mention that when the axillary vein was ligated, the general blood pressure rose about 10 points. All bleeding points were controlled during the operation with sutures and ligatures of silk. The cephalic vein was dilated to a diameter of about 1 cm. The subcutaneous tissue and skin were closed with interrupted sutures of silk.

Immediately after the operation the hand which formerly had felt cold now had good color and was warm. There was unquestionably an immediate improvement in the circulation through the procedure followed.

Fig. 11.—The operation as completed in two stages. The ligatures are numbered in the order of their application.

The great difficulty encountered in the second operation, which was tedious and required six hours, was further proof that it would have been inadvisable to have attempted more at the first operation.

The ligations during the first operation were of the external and internal jugular, subclavian and innominate veins and the subclavian artery; and during the second operation of the axillary and long thoracic veins and subclavian, axillary and long thoracic arteries, a total of ten ligations (fig. 11).

Postoperative Notes.—On Aug. 11, 1928, the first dressing was applied.

On August 11, 3 a. m.: The patient felt well. There was no pain in the right hand or arm, which seemed even warmer than the other. The dressings which were loose were removed: a slight serosanguineous discharge was noted. The tissues were quite boggy in the region of the wound, suggesting edema. During

the operation it was noted that there were frequent little bursts of clear fluid into the wounds, apparently from dilated lymph vessels. The patient complained of being hot. Examination revealed a blood pressure of 170 systolic and 110 diastolic. A dry dressing was applied.

August 11, 10 a. m.: The wound was dressed. There was boggy swelling, suggesting accumulation of fluid in the wound. A probe was introduced into the wound and a considerable amount of almost clear fluid was evacuated. A dry dressing was applied. The blood pressure was 136 systolic and 84 diastolic. It was evident that the peak of the postoperative rise in blood pressure would have been missed if a reading had not been made during the night (3 a. m.). The pulse in the right radial artery was easily palpable for the first time since the patient was first seen; the rate was 84.

August 12: The dressing had to be changed on two occasions because of the marked serous discharge from the wound. No bleeding occurred. A few stitches were removed. The blood pressure was 164 systolic and 86 diastolic; the pulse was 86.

August 13: The remaining stitches were removed. The wound was in good condition, and no discharge had occurred since the day before. Apparently, there

Fig. 12 (November, 1928).—Complete cure, three months after the second operation. The circumferential measurements of both arms is the same. The patient writes, "I am feeling perfectly well."

was no further fling up of the wound. The blood pressure was 166 systolic and 84 diastolic; the pulse rate was 88. A dressing was applied.

From this time on, the progress of the patient was uneventful, with the exception of the development of an extensive thrombophlebitis of the veins of the anterior wall of the chest and of the upper arm. The condition subsided with rest in bed, immobilization of the arm and hot fomentations.

September 12: The patient left for Mexico. No thrill could be felt nor bruit heard. The shoulder and arm were steadily decreasing in size. The patient was feeling stronger daily. The blood pressure was 130 systolic and 86 diastolic. The pulse rate was 76.

November 11: The patient wrote: "I am feeling perfectly well and my arm is recovering its life. It is a little stiff but its size is normal at this time, as you will notice from the enclosed picture" (fig. 12).

COMMENT

Thompson, in his classic monograph on subclavian aneurysm, said that "ligature of the first part of the subclavian artery has turned out to be a very unsatisfactory operation. It is both difficult and dangerous.

The artery is very short, numerous branches arise from it, it is very deeply situated and is surrounded by important veins and nerves. The internal jugular and vertebral veins are directly in front of it; also the pneumogastric and phrenic nerves. At its origin, the right innominate vein forms an anterior relationship." I believe that the reason this procedure has proved so difficult is that the surgeon has attempted this ligation without first performing a subperiosteal resection of the inner half of the clavicle. By this step, a very difficult approach is rendered much more accessible.

In an arteriovenous fistula the pulse is smaller on the injured side showing that the volume of arterial blood is less, while the dilated veins show that the venous blood is increased.

The retardation of the pulse rate on closure of the fistula by digital pressure or by permanent suture or ligation was explained by Holman as follows: "Closure of the fistula results in a filling up of the aorta by the volume of blood which formerly leaked through into the veins.

TABLE 2—Circumferential Measurements During Second Stage of Treatment, 1928

	Jan 2	Feb. 28	Aug. 6	Nov 12
Area	Cm.	Cm.	Cm.	Cm.
Wrist	17.0	17.0	17.0	16.5
Middle forearm, 14 cm. above the wrist	28.0	28.0	27.0	24.0
Elbow	32.0	32.0	32.0	28.0
Middle arm just below greatest swelling	38.0	38.0	37.5	31.5
Over greatest swelling upper third arm.	41.0	41.0	41.0	35.5
Axilla	45.0	45.0	45.0	42.5
Right side of chest at level of midline	52.5	52.5	54.0	54.0
Left side of chest at level of midline	51.0	51.0	52.5	52.0

This produces an increase in aortic pressure which in turn stimulates the depressor fibers of the vagus in the arch of the aorta and reflex slowing of the heart is the result."

Holman and Dock have definitely shown, in experimenting with animals, that in an arteriovenous fistula the cardiac output is doubled. This observation is interesting as it differs from that of Lewis who stated "that the output in an arteriovenous fistula does not appear to be unusually altered."

Holman was among the first to emphasize the physiologic basis for the alteration in blood pressure by opening and closing the fistula, giving as his explanation an increase in the total volume of blood during the existence of the fistula.

Conditions in the fistula that determine or influence the systemic effects are, according to Matas: (a) the size of the arteriovenous fistula; (b) the volume and force of the arterial stream that is short-circuited into the communicating vein; (c) the caliber of the vessels involved; (d) the proximity to the heart; (e) the duration of the fistula; (f) the age of the patient, and (g) the coexistence of the antecedent cardiovascular disease.

It is always to be remembered that gangrene occurs much more frequently in an arteriovenous than in a saccular aneurysm. I believe that in an arteriovenous aneurysm simultaneous ligation of the accompanying vein with the artery should always be executed. This would appear at first thought to be paradoxical. Indeed, it reverses a surgical principle long emphasized by writers of textbooks. The special needle or ligature carrier was invented with the main idea of being able to ligate the artery safely without injury to the satellite vein. To ligate unhesitatingly a normal and large vein is contrary to tradition. Tradition is not easy to set aside.

I believe, however, that there is now sufficient experimental and clinical proof that this procedure today should be a recognized rule. Professor Tuffier, the great French surgeon, said that "ligation of the correspondingly healthy vein" should be executed "in all cases of ligation of the great vessels of the root of the limbs." Sir George Makins, the eminent British surgeon, long an authority in surgery of blood vessels, stated that "the elimination, in fact, of the capacious main vein is a real advantage, since this for the time affords a too ready channel of exit for the diminished arterial supply, as well as an undesirable reservoir for stagnation." He concluded, "these considerations have led me not only to regard obligatory simultaneous occlusion of a main artery and vein as a negligible factor in the risk of gangrene of a limb; but to hold further, that the procedure is preferable whether the vein be wounded or not; the result of the combined procedure being to maintain within the limb for a longer period the smaller amount of blood supplied by the collateral arterial circulation, and hence to improve the conditions necessary for the preservation of the vitality of the limb." In accord with this procedure but disagreeing with Makin's explanation, Brooks and Martin stated that the increase in the peripheral blood pressure is the principal beneficial result of ligating the vein. Reid and Holman's observations support the latter view. Holman, in his brilliant experimental work, repeatedly proved the necessity of this simultaneous ligation of vein and artery.

In the light of this knowledge one must accept the view that some degree of equilibrium of the arterial and venous systems must be preserved. I believe that the following maxims may be laid down for the prevention of gangrene: 1. In an arteriovenous fistula or aneurysm it is imperative to ligate the accompanying vein if the artery is ligated. 2. In a simple aneurysm it is at least advisable to do so.

Few or none of these patients should be operated on until from three to six months have expired unless the cardiovascular effects are conspicuous and progressive. Then if the fistula still exists, further delay is not indicated. The reasons for waiting are (*a*) the possibility of a spontaneous closure of the artificial communication with cure, and

(b) the possibility of awakening a lurking infection if the operation follows the injury too soon. Infection usually results in death.

"Common errors in the treatment of aneurysms," according to Halsted, "are the following: (1) opening the sac or pulsating hematoma without first making a temporary occlusion of all the possible sources of hemorrhage; (2) the permanent ligation of a great arterial trunk as a precautionary measure in the search for a distal bleeding point; (3) ligation of a trunk too far from the aneurysm; (4) stuffing the wound with gauze to arrest hemorrhage; (5) drainage; (6) the employment of catgut for the ligature, or of silk that is too fine, and (7) ligation of the artery proximal to an arteriovenous aneurysm or fistula."

Surgeons attempting to intervene in aneurysms or arteriovenous fistulas should be much more concerned with hemostasis and meticulous technic than with the duration of the operation. These operations are at best always tedious and time-robbing and demand the best of the surgeon's skill. Without profuse hemorrhage these patients stand operations of six or seven hours' duration without severe shock. "An operator searching for a bleeding point in a pool of blood, and particularly so when embarrassed in his movements by the adherent walls of an aneurysm within which he is working so disadvantageously, presents a distressing spectacle. I would rather devote an additional hour or more to an operation than be caught for a few moments in such a predicament" (Halsted). The reestablishment of a normal vascular equilibrium is the objective sought.

SUMMARY

A case of traumatic subclavian arteriovenous aneurysm of eight years' duration showed:

1. Enormous swelling of the right side of the chest, the right portion of the shoulder girdle and the entire right arm and hand, with great distention of veins in these parts.
2. Cardiac dilatation and hypertrophy resulting from increased volume flow through the heart incident to the production of the fistula.
3. Branham's bradycardiac reaction and associated variations in blood pressure due to an increase in blood volume caused by the fistula.
4. Characteristic bruit and thrill transmitted centrifugally.
5. Increase of oxygen content in veins distal to lesion.
6. Dilation of the proximal artery, diminution of the distal artery and great dilatation and thickening of the distal vein.
7. That proximal ligations of artery and veins improved the condition but did not effect a cure.
8. That subsequent distal ligations, ten months later, completing the quadruple ligation, effected a cure.

It is always to be remembered that gangrene occurs much more frequently in an arteriovenous than in a saccular aneurysm. I believe that in an arteriovenous aneurysm simultaneous ligation of the accompanying vein with the artery should always be executed. This would appear at first thought to be paradoxical. Indeed, it reverses a surgical principle long emphasized by writers of textbooks. The special needle or ligature carrier was invented with the main idea of being able to ligate the artery safely without injury to the satellite vein. To ligate unhesitatingly a normal and large vein is contrary to tradition. Tradition is not easy to set aside.

I believe, however, that there is now sufficient experimental and clinical proof that this procedure today should be a recognized rule. Professor Tuffier, the great French surgeon, said that "ligation of the correspondingly healthy vein" should be executed "in all cases of ligation of the great vessels of the root of the limbs." Sir George Makins, the eminent British surgeon, long an authority in surgery of blood vessels, stated that "the elimination, in fact, of the capacious main vein is a real advantage, since this for the time affords a too ready channel of exit for the diminished arterial supply, as well as an undesirable reservoir for stagnation." He concluded, "these considerations have led me not only to regard obligatory simultaneous occlusion of a main artery and vein as a negligible factor in the risk of gangrene of a limb; but to hold further, that the procedure is preferable whether the vein be wounded or not; the result of the combined procedure being to maintain within the limb for a longer period the smaller amount of blood supplied by the collateral arterial circulation, and hence to improve the conditions necessary for the preservation of the vitality of the limb." In accord with this procedure but disagreeing with Makin's explanation, Brooks and Martin stated that the increase in the peripheral blood pressure is the principal beneficial result of ligating the vein. Reid and Holman's observations support the latter view. Holman, in his brilliant experimental work, repeatedly proved the necessity of this simultaneous ligation of vein and artery.

In the light of this knowledge one must accept the view that some degree of equilibrium of the arterial and venous systems must be preserved. I believe that the following maxims may be laid down for the prevention of gangrene: 1. In an arteriovenous fistula or aneurysm it is imperative to ligate the accompanying vein if the artery is ligated. 2. In a simple aneurysm it is at least advisable to do so.

Few or none of these patients should be operated on until from three to six months have expired unless the cardiovascular effects are conspicuous and progressive. Then if the fistula still exists, further delay is not indicated. The reasons for waiting are (*a*) the possibility of a spontaneous closure of the artificial communication with cure, and

(b) the possibility of awakening a lurking infection if the operation follows the injury too soon. Infection usually results in death.

"Common errors in the treatment of aneurysms," according to Halsted, "are the following: (1) opening the sac or pulsating hematoma without first making a temporary occlusion of all the possible sources of hemorrhage; (2) the permanent ligation of a great arterial trunk as a precautionary measure in the search for a distal bleeding point; (3) ligation of a trunk too far from the aneurysm; (4) stuffing the wound with gauze to arrest hemorrhage; (5) drainage; (6) the employment of catgut for the ligature, or of silk that is too fine, and (7) ligation of the artery proximal to an arteriovenous aneurysm or fistula."

Surgeons attempting to intervene in aneurysms or arteriovenous fistulas should be much more concerned with hemostasis and meticulous technic than with the duration of the operation. These operations are at best always tedious and time-robbing and demand the best of the surgeon's skill. Without profuse hemorrhage these patients stand operations of six or seven hours' duration without severe shock. ABSTRACT OF DISCUSSION

DR. HERMANN B. GESSNER, New Orleans: Dr. Gilcreest is to be congratulated, not only on the skill with which he treated this patient, but on the thoroughness with which he reviewed the symptomatology and pathology of the condition. In my experience with arteriovenous aneurysms, which has been limited to those of the lower extremity, I have been able in some cases to control the fistula by attacking it from the venous side. I remember one interesting case in which the vein involved was a vena comes. I was able to incise the vein, suture the orifice with paraffinized silk, and then sacrifice the vena comes.

I think one diagnostic sign is worth bringing out. Dr. Gilcreest did not mention it, probably because the diagnosis in his case was so clear. I refer to the sign I have learned from my teacher and friend, Dr. Rudolph Matas: It is the change in the distal pulse, the Delbet sign. I can recall two cases in which the diagnosis was made in that way. One was a case of aneurysm of the popliteal artery. No bruit was discernible. A mass was present. It was not possible to find the pulsation of the tibial arteries. I presented this patient to a class and Dr. Matas operated, confirming the diagnosis. The explanation was simple. The aneurysm was so filled with clot that there was little movement of blood.

In a case of aneurysm of the forearm seen recently, the patient had a hematoma that permitted the diagnosis by means of a needle. There was no pulsation and no bruit; yet, on incising the hematoma, arterial blood came out, escaping from a wound of the radial artery. I think it important to realize that aneurysms may be recognized on this Delbet sign.

It happens not infrequently that an aneurysm is incised under the diagnosis of abscess. I know of a case in which an aneurysm of the subclavian artery was incised in that way. The patient had pain and tenderness, a rise in temperature and leukocytosis. A colleague of mine opened the aneurysm in the belief that it was an abscess. I think this diagnostic point should be brought out and carefully considered, as tending to prevent such errors.

DR. ALBERT O. SINGLETON, Galveston, Texas: Through his persistence in this case Dr. Gilcreest has obtained an excellent result. Arteriovenous aneurysms are more of a problem than the sacculated aneurysms. Probably in Dr. Gilcreest's case he performed part of the operation and hoped for success, and then did the other part subsequently, rather than completing it all at once. He has shown that the operation took a long time, and I do not think that he is necessarily a slow operator. Any one who has operated in these cases realizes that although time passes rapidly, the surgeon often does not get far.

I appreciate Dr. Gessner's remarks about the diagnosis, and think they should be repeated often. In the usual run of work, these cases are not seen frequently, and these points are sometimes forgotten. The aneurysm varix has an opening, which makes the problem more difficult than in the case in which Dr. Gessner was able to suture the aneurysm from within the vein. I have been helped in two or three cases in making a differential diagnosis between aneurysm varix and arteriovenous aneurysm by injecting sodium iodide into the artery, and then making a roentgenogram to show the direct communication. This method also shows the collateral circulation in its approximation to the sac. In one case it showed that there was a considerable interval and a sac between the artery and the vein.

Dr. Gilcreest, I think, is right in ligating the vein at the same time as the artery. I had a patient with an aneurysm at the lowest part of the external iliac artery, on which I intended to perform a double ligation. On exposing it, however, above the aneurysm and clamping the artery I saw such an immediate blanching of

the foot that it was evident that an ischemic gangrene would probably develop if I ligated the artery alone. On clamping the vein, the warmth of the foot promptly returned. I ended by ligating both of the vessels, and the circulation was not much interfered with. The leg remained warm and continued warm until a subsequent ligation resulted in a perfect cure.

DR. W. LOWNDES PEPLE, Richmond, Va.: I also wish to congratulate Dr. Gilcreest on his perseverance and success, and wish to show you a recent case of aneurysm of the femoral artery, which occurred in a man about 22 years old, who had been shot with a 22 caliber rifle about ten years before. He was not ill at the time, there was no swelling, he resumed all of his activities, athletics and so forth, and had no trouble for nine years. He then began to have attacks of pain in the region of his heart. Six weeks before his admission to the hospital he had violent pain over the region of the iliac artery. All of the typical signs and symptoms of a fistula were obtained. The x-ray picture showed an enormously large artery pulled to one side, the femoral vein accompanying it also pulled to one side, and the vein which lay beneath it was visible. One could see the small aneurysm, about the size of a pigeon's egg. It was as though the drift of the arterial blood driven across the vein has caused this sacculatation. The man was a good patient, young, strong and thin; it was possible, therefore, to ligate the artery above and below, and ligate the normal femoral vein above and below. We then dissected out the sac. There were several veins opening into this which were easily tied.

I am glad to see that the other speakers have no doubts whatever about the advisability of ligating even the normal accompanying vein. This seems to be now an ordinary procedure, which one might speak of as stabilization of the vein. There was no reaction in the dorsalis pedis artery or the posterior tibia which was apparently normal on both sides. The patient made an uneventful recovery.

DR. J. L. CAMPBELL, Atlanta, Ga.: I suppose that the surgical division of the Grady Hospital is the best place in the world to find injuries to blood vessels. I recall twenty-five or thirty patients who have been operated on for this condition in my service, and most of these cases were of the arteriovenous type. I operated on a patient for subclavian aneurysm a number of years ago, and am glad to know that Dr. Gilcreest recommends resection of the clavicle. I do not think that one can operate adequately without this space. In my case I succeeded in curing the patient, in whom the condition was quite recent, by proximal ligation. The patient was a negro and I was unable to keep track of him.

The next case was that of an aneurysm of the common carotid artery in which an arteriovenous aneurysm had occurred. In that case I succeeded in restoring both vessels and the patient recovered.

The next case was that of a subclavian aneurysm in which I attempted to restore the lumen of both vessels. I had just the condition that Dr. Peple showed, with dilation of the vein. I applied a suture and attempted to make the separation so that I could close it. The patient became weak and the anesthetist said that I had better stop. Unfortunately, the patient died. That is the only patient that I have lost.

I have had two cases of aneurysm of the profunda and two of the femoral artery. In one of these I attempted to restore the lumen of the vessel, and gangrene resulted. In the other case I did not see the patient until after the limb had been amputated. I have had one aneurysm at the bend of the elbow, and two or three in the popliteal space. When the patients are seen early I think proximodistal ligation should be performed. If they are seen later, but when the vessels can be cleared and the patient is in good condition, I think that the

lumen can be restored without much difficulty. In one case of a pulsating exophthalmos I succeeded in partially occluding the internal carotid artery with a band, and relieved the patient of all his symptoms.

These cases are interesting. Any time the physicians present happen to be in Atlanta, I shall be glad to show them some of the cases. There nearly always are several in the hospital.

DR. GEORGE TULLY VAUGHAN, Washington, D. C.: I listened with great pleasure to Dr. Gilcreest's account, for I have had much experience with aneurysms of various kinds. Dr. Campbell just said that he was foolish enough to try to close the wounds and vessels in one patient and the patient died. Perhaps if he had closed the wounds the patient would not have died. I was foolish enough to try the same thing a number of years ago. A patient had just been shot through Scarpa's triangle. The injury happened on a street car and someone stuck a handkerchief into the wound. I watched the case and for two weeks there was no sign. Then an aneurysm varix developed, with a bruit. I operated and found a wound in the vein and artery, also four points in vessels filled with lymph. I closed these openings with fine vaselized sutures. The patient is living today, after fourteen years, and has no trouble with his extremities.

So many surgeons have spoken of the necessity of ligating both vessels, that they occlude the veins. This may be necessary occasionally, but not always. I have operated on many patients and have performed the Matas operation on several occasions, filling in the walls of the vessel sac so as to close the vessel completely, and not touching the vein. I have done this on the external iliac, the iliac, and on the femoral arteries and have not seen a case of gangrene. I have had probably a dozen cases of this kind.

I wish to ask Dr. Gilcreest why he did not find the openings in these two vessels and sew them up instead of using so many ligatures.

DR. WALTER C. G. KIRCHNER, St. Louis: I wish to congratulate the essayist on this splendid piece of surgery. Three years ago I ligated a subclavian artery in the first portion, I wish to mention a few points in differential diagnosis. This case was also a gunshot wound, the aneurysm having enlarged and become engorged on the vessels of the neck. It was present on the left side. There was no pulsation in the right pulse. There was atrophy on the one side, in addition to the enlargement on the other. In other respects there were all the characteristic signs of aneurysm. Careful dissection was made under general anesthesia. It was possible to ligate the first portion of the subclavian artery near the aortic arch without resecting the clavicle. In fact, that was the easiest part of the operation. The more difficult part, a fact that I can appreciate greatly, is the opening of the sac and the treatment of the condition when the hemorrhage is present. Unless one has had that experience he cannot realize how difficult it is to find these structures. In the aneurysm there is a lot of fibrous tissue and a lot of disarrangement of structures. This explains why so much time is necessary in handling these cases.

DR. GILCREEST: I am naturally pleased that the report of this case excited such extensive discussion.

Referring to Dr. Gessner's mention of Delbet's sign, it will interest him to know that the patient's radial pulse was practically imperceptible, which is consistent with what Dr. Gessner pointed out; it became palpable only after the second operation.

I am glad to note that Dr. Singleton also appreciated that to carry out this technic correctly consumes much time. The cases reported by him and Dr. Peple are of great clinical significance.

The large series of operations by Dr. Campbell are most unusual. I do not know anywhere in the country where such a wealth of records of vascular surgical procedures could be found. I shall indeed avail myself of Dr. Campbell's invitation to see some of these patients the first time I revisit Atlanta.

Answering Dr. Vaughan's question of why I did not find the openings into the arteries and veins and sew them up, instead of resorting to so many ligatures, I can only repeat what I said before, that to have attempted this procedure through such a wilderness of large dilated thin-walled veins would have been only to produce profuse hemorrhage and court disaster. Dr. Kirchner emphasized this in his remarks.

THE CELIAC PLEXUS AND ITS BRANCHES *

F. KISS, M.D.

BUDAPEST, HUNGARY

AND

HARRY C. BALLON, M.D.

ST. LOUIS

Modern surgery through the use of local anesthesia has focused attention on the celiac plexus. At first, the chief concern was merely to develop a technic for making injections into this plexus which would permit the carrying out of certain major operations under local anesthesia. This led to the recording of new observations concerning its physiology. Relatively little attention has been paid, however, to the exact macroscopic and microscopic appearance of this region in the light of recent surgical experiences. Some of the disturbances referable to the duodenum and the pancreas which make their appearance after operations on the gallbladder and other abdominal operations require an exact anatomic knowledge of the celiac plexus for their proper understanding. So, too, attacks of abdominal pain simulating pain due to gallstones can be better differentiated from pancreatic, celiac and other types of medical and surgical pain, if one appreciates more fully the histologic character and ramifications of this plexus.

The modern surgeon still refers to the anatomic plates of the celiac plexus executed during the past century by Hirschfeld-Leveillé,¹ Henle,² Testut,³ Poirier,⁴ Quain⁵ and others, since nowhere in the newer literature is there to be found any record of a recent systematic investigation of the plexus as a whole. Even the work of Hirt⁶ (1924) is concerned only with the innervation of the kidney and the suprarenal gland, while Raigorodsky⁷ (1928) described only the branches of the

hepatic plexus. The well known illustrations which are to be found in textbooks give, in general, a clear idea of the topography of the branches of the plexus. But they are more or less schematic, do not concern the innervation of the pancreas and the duodenum and do not treat of the plexus in relation to surgical procedures.

This stimulated us to investigate the celiac plexus from the standpoint of modern surgery, which we did with the help of the newest macrotechnical methods. We carried out our investigations on thin adult human cadavers. In animals, the topography and distribution of the plexus are extremely variable, so that the anatomic relationships, as well as the physiologic results, obtained from dissections and investigations carried out on animals cannot be compared with those obtained in man. It has been our aim in this study to present a systematic description of the plexuses and their connections without exact reference to topographic details.

TECHNIC

We dissected under slowly dripping water, and we also employed the acidol pepsin digestion method with good results.⁸ The dissection was also carried out on specimens that were not fixed and which were kept in cold running water during a period often of from two to three days or more. This loosened the collagen fibers. The cleanly prepared nerves were later colored by the method described by Gyermek⁹ of this institute in 1919.

In the preparation of fine nerves there is always the danger of calling adjacent lymph vessels, small veins and connective tissue fibers, nerves. To avoid this, we compared several specimens prepared one after another, and controlled the relation of the nerves, as well as of the ganglions, with one another.

In addition to the celiac ganglions, well known treatises also describe the celiac plexus, which they consider the central part of the whole system. The following are mentioned as individual parts of the plexus which go to the various organs: (1) plexus phrenicus or plexus diaphragmaticus, (2) plexus aorticus, (3) plexus suprarenalis, (4) plexus renalis, (5) plexus spermaticus, (6) plexus gastricus superior and inferior, (7) plexus hepaticus, (8) plexus lienalis, (9) plexus mesentericus superior, (10) plexus mesentericus inferior and (11) plexus pancreaticus. We, for the most part, employ this grouping.

In our description, we will consider: (1) the celiac ganglions, (2) the roots of the celiac ganglions, (3) the branches of the celiac ganglions and (4) the microscopic structure of the celiac plexus.

8. Two pastils of strong acidol pepsin are dissolved in 200 cc. of water. The field of dissection is kept well moistened with this solution. It is applied either by tampons or by pipet and, if necessary, over a period of from two to three hours. This makes the removal of connective tissues considerably easier.

9. Gyermek: *Farben makroskopisch-anatomischer Präparate*, Ztschr. f. wissenschaftl. Mikr. **35**:45, 1918.

THE CELIAC GANGLIONS

In most instances, we found a flat ganglion the size of a strawberry on each side of the celiac artery (figs. 1, 2 and 3), the form of which may be variable. We sometimes found two, three or more smaller ganglions on each side (fig. 4). The ganglions on one side are united to those on the other by many transverse fibers above and below the celiac artery, in front of the aorta (fig. 1). In the majority of cases, however, an unpaired ganglion lies under the celiac ganglions directly on the aorta (fig. 3 18). Many authors call this ganglion the ganglion aorticum or, because of its union with the renal plexus, the ganglion aorticorenale. The other ganglions in this region, which we have illustrated in our figures, belong to the diaphragmatic and renal plexuses. The celiac ganglions form the central point for the celiac plexus.

THE ROOTS OF THE CELIAC PLEXUS

The roots of the celiac plexus are formed by the nervi splanchnici majores and minores and both vagi. Figures 1 and 2 and figure 3 2 and 2a show clearly the course of the splanchnic nerves. It is of practical importance to note the lengthy course (from 8 to 10 cm.) of the nervus splanchnicus major (fig. 3 2) behind the lumbar portion of the diaphragm. Surgical procedures also make use of this fact. Thus, the splanchnic nerves are infiltrated transdiaphragmatically in the space between the vertebral column and the lumbar portion of the diaphragm. In that the splanchnic minor (fig. 3 2a) lies close to the splanchnic major, it is of course blocked by the same injection. In this way (as will be seen in the paragraph dealing with the microscopic structure of the plexus), all the sensory roots of the celiac plexus are blocked. Figure 3 3 shows that after the splanchnic major perforates the diaphragm, it then turns in a right angle medially and ends in the celiac ganglion.

One reads in most textbooks (for example, that of Spalteholz¹⁰) that the left vagus does not always take part in the formation of the celiac plexus. We, however, found in every specimen that both vagi contributed many branches to the formation of the plexus (fig. 1 3).

Spalteholz pointed out that the upper lumbar ganglions of the sympathetic send fibers to the plexus. Because of the proximity of the plexus to the ganglions, this would seem quite possible. We found no such branches.

THE BRANCHES OF THE CELIAC PLEXUS

We desire to draw special attention to the linking branches between the celiac ganglions of both sides (fig. 1) which lie in front of the

10. Spalteholz: Handatlas der Anatomie des Menschen, Leipzig, S. Hirzel, 1895-1903.

aorta, surround the celiac artery and form a dense plexus. The older descriptions lead one to the erroneous belief that both celiac ganglions sometimes form a single semilunar ganglion. We did not observe this in any specimen. As we have already pointed out, the celiac ganglions form with their branches the center and chief plexus of nerves going to the abdominal organs. The splanchnic nerves enter the ganglions, while the fibers of both vagi either end in these linking branches or run direct to the plexuses in the organs. All sympathetic and sensory fibers of the celiac plexus arise either from the ganglion bodies or from the linking branches. This explains why infiltration of the celiac ganglions results in complete anesthesia of the area between the diaphragm and the pelvis.

We refer briefly to the following plexuses of nerves going to the various abdominal organs.

Plexus Phrenicus (figs. 1 and 2).—This small plexus lies on the anterior part of the lumbar portion of the diaphragm in the region of the inferior phrenic artery. The roots of this plexus arise directly from the celiac ganglions. We found the ganglion phrenicum, which is the size of a small pea, on both sides (fig. 1 12). On the left side, the ganglion phrenicum lies in closer relation to the celiac ganglion. Luschka,¹¹ in 1853, described the relation of this ganglion with the phrenic plexus and phrenic nerve. We observed the same relationship in every specimen. But the phrenic plexus and the sympathetic nervous system play no part in the motor innervation of the diaphragm. Our microscopic investigations have shown that the branches of this plexus consist mostly of nonmedullated sympathetic fibers, and that between the sympathetic fibers only solitary medullated fibers are to be seen. The sympathetic fibers run to blood vessels and to the suprarenal glands, while the medullated fibers unite the region of the celiac plexus with the phrenic nerve and through the phrenic nerve with the cervical plexus. This is the route through which "pain" from the region of the celiac plexus (liver, pancreas, kidney, stomach and intestinal canal) reaches the plexus in the cervical region and produces reflex pain in the shoulder. In support of our observation is also the fact that, after splanchnic anesthesia, the movement of the diaphragm is in no way affected either by the development of a partial paralysis or by other functional disturbances.¹²

Plexus Suprarenalis (figs. 1 13 and 2 9a).—The many roots of this plexus arise from the celiac ganglion and from the phrenic and renal plexuses. We found no macroscopic ganglions in this plexus. Accord-

Fig. 1.—Plexus coeliacus (splanchnic—deep level). Figures 1 and 2 are taken at different levels. 1 indicates truncus sympathicus; 2, nervus splanchnicus major; 3, nervus vagus (right); 4, nervi intercostales; 5, ribs; 6, diaphragm; 7, suprarenal gland (right); 8, pancreas (body), retracted to the left; 9, kidney; 10, plexus aorticus; 10a, aorta; 11, plexus phrenicus (diaphragmaticus); 12, ganglion phrenicum; 13, plexus suprarenalis; 14, ganglion coeliacum (right); 15, plexus renalis and renal artery; 16, cardia ventriculi; 17, plexus cardiacus; 18, gastric artery (left); 19, plexus coeliacus and coeliac artery; 20, ganglion coeliacum (left); 21, plexus pancreatis (left portion); 22, plexus lienalis and splenic artery, and 23, plexus mesentericus superior and superior mesenteric artery.

Fig. 2.—Plexus coeliacus (superficial level). 1 indicates liver, lobus caudatus (Spigelii); 2, esophagus; 3, stomach; 4, diaphragm; 5, ductus hepaticus; 6, hepatic artery; 7, plexus hepaticus; 8, plexus cardiacus; 9, suprarenal gland (left); 9a, plexus suprarenalis sinister; 10, ganglion coeliacum sinister; 11, plexus lienalis and splenic artery; 12, aorta; 13, plexus mesentericus superior and superior mesenteric artery; 14, plexus duodenalis (in part); 15, caput pancreatis; 16, plexus pancreatis (right portion); 17, pylorus, and 18, duodenum.

Fig. 3.—Plexus coeliacus, seen from the right. 1 indicates truncus sympathicus dexter; 2, nervus splanchnicus major; 2a, nervus splanchnicus minor; 3, nervus splanchnicus major perforating the diaphragm; 4, liver; 5, gallbladder (pulled to left); 6, vena cava inferior; 7, diaphragm (lumbar portion); 8, plexus hepaticus (posterior view); 9, caput pancreatis (pulled over to left); 10, plexus pancreatis (posterior view); 11, duodenum (pulled to left, posterior view); 12, peritoneal covering of duodenum; 13, ganglion coeliacum dexter; 14, plexus renalis dexter and renal artery; 15, vena cava inferior (pulled to right, posterior view); 16, aorta with plexus aorticus; 17, kidney (right), and 18, ganglion aorticum.

Fig. 4.—Plexus hepaticus, pancreaticus and duodenalis. 1 indicates liver; 2, esophagus; 3, stomach, cardia; 3a, pylorus; 4, gallbladder; 5, ductus hepaticus and plexus hepaticus; 6, hepatic artery and plexus hepaticus; 7, plexus cysticus; 8, plexus py'oricus; 9, gastroduodenal artery; 10, caput pancreatis; 11, plexus pancreaticus; 12, duodenum; 13, plexus duodenalis; 13a, plexus duodenalis (left portion); 14, plexus mesentericus superior and superior mesenteric artery; 15, gastric artery (left); 16, ganglion coeliacum dexter; 17, ganglion coeliacum sinister, and 18, splenic artery.

ing to Hirt,⁶ the individual fibers of the plexus run through the left suprarenal gland toward the renal cortex.

Plexus Renalis (figs. 1 15 and 3 14).—The roots of this plexus arise from the celiac ganglion, from the uniting branches between the right and the left celiac ganglions and from the aortic plexus. We always found several ganglions in the plexus, varying in size from that of a millet seed to that of a pea. The branches follow the renal arteries.

Plexus Aorticus (figs. 1 10 and 3 16).—This is a dense plexus on both sides of the abdominal aorta with many linking branches between both sides. Its chief branches arise from both trunks of the sympathetic, from the celiac plexus and from both renal plexuses. The aortic plexus sends branches to the inferior mesenteric plexus and to the spermatic plexus (latter not illustrated in the figures).

Plexus Cardiacus and Plexus Pyloricus (figs. 1 17, 2 8, 4 8 and 5 1).—The descriptions hitherto make mention of a gastric plexus or a superior and an inferior gastric plexus. We constantly found that the nerves reach the stomach at the cardia and at the pylorus, so that it is preferable to speak of a cardiac and a pyloric plexus.

The cardiac plexus is formed by branches of both vagi and by branches from the celiac plexus. Accessory branches come from the celiac ganglions, from its uniting branches and from the hepatic plexus. It forms a small plexus, which encircles the gastric artery, and which runs to the cardiac portion of the stomach. Here it meets the branches of both vagi.

The pyloric plexus (fig. 4 8) comes from the hepatic plexus and from the plexus that winds around the gastroduodenal artery (fig. 4 9). The roots of the last mentioned plexus arise partly from the hepatic plexus and partly directly from the celiac plexus. The branches penetrate obliquely into the wall of the stomach.

We do not wish to make any lengthy clinical digressions in this report. But the description that has been given suggests that certain derangements after operations on the stomach may be explained on a purely anatomic basis, particularly the normal correlated action of pylorus and cardia. When one appreciates that gastrojejunal ulcer develops more frequently when a gastro-enterostomy has been performed on a normal stomach than when it has been performed for ulcer, and that amputation neuromas may be demonstrated at the base of gastric ulcers, then it seems not unlikely that at least some of the disturbances noted, particularly after extensive operations on the stomach, are to be attributed to the destruction of important nerve fibers. This may be caused either directly through degeneration of nerve fibers or indirectly by the formation of scars. Certain it is, however, that extensive resec-

tions of the stomach are not possible without destruction of important nerve fibers.

Plexus Lienalis (figs. 1 22, 2 11 and 4 18).—The roots of this plexus come from the celiac plexus, from the cardiac plexus and from the superior mesenteric plexus. Single branches come directly from the left celiac ganglions. The splenic plexus directs itself with the splenic artery to the spleen. On its way, this plexus gives off many branches to the pancreas (fig. 1 21). We found no macroscopic ganglions in this plexus.

Hepatic Plexus (figs. 2 7, 3 8, 4 5, 6 and 7 and 5 4).—The hepatic plexus is a rich plexus that lies in the hepatoduodenal ligament, and surrounds the hepatic artery, portal vein, hepatic duct and common bile duct. As many fibers run anteriorly to these structures as posteriorly; for this reason Raigorodsky,⁷ in a new description, distinguished an anterior and a posterior hepatic plexus. The fibers which go to the gallbladder form a small cystic plexus in the region of the cystic duct (fig. 4 7). The roots of the hepatic plexus arise from the right celiac ganglion and from the fibers which unite both celiac ganglions, from the aortic plexus and from the right renal plexus. The hepatic plexus sends branches to the liver, gallbladder, suprarenal glands, pyloric end of the stomach and head of the pancreas. We found no macroscopic ganglions in this plexus.

Raigorodsky differentiated four types of hepatic plexus after the four types of hepatic artery described by Rio-Branco.¹³ One of us (F. K.¹⁴) recently described twenty-four variations of the hepatic artery, and we were able to compare our nerve specimens with his original specimens. We found that several branches of the hepatic plexus always follow the abnormal branches of the hepatic artery. The main part of the plexus, however, is situated even in such cases on the anterior and posterior surfaces of the common duct and the portal vein.

The purpose of the following is merely to point out that certain clinical applications can be made of our anatomic observations. We mention some of them:

Relatively little damage is done to the important nerves in operations confined to the cystic duct.

In operations on the common bile duct, it is possible to damage important nerve fibers. It is true that in conditions involving the common duct, the pain is often pancreatic in origin. This need not,

13. Rio-Branco: *Essay sur l'anatomie et la médecine opératoire du tronc coeliaque*, Paris, 1912.

14. Kiss and Mihálik: *Ueber die Zusammensetzung der peripherischen Nerven und den Zusammenhang zwischen Morphologie und Funktion der peripherischen Nervenfasern*, *Ztschr. f. Anat. u. Entwgesch.* 88:112, 1928.

however, necessarily be so. If the same pain for which the patient was operated on persists, it is, of course, impossible to exclude with absolute certainty a pancreatic origin, even though the pancreas is clinically normal, particularly since the common bile duct is so closely related to the head of the pancreas. It is for this reason, too, that patients with conditions involving the common duct often complain of pain in the back. This pain can frequently not be differentiated from pancreatic pain or celiac neuralgia. That there should be pain in the back and vertebral tenderness is to be expected, since the gland, as well as important nerve fibers, lies retroperitoneally. Should, however, a new type of pain make its appearance after operation, one must always appreciate the possibility of some inflammatory or degenerative process involving the pain-bearing fibers which surround the common duct and should remember that this may be as frequent an occurrence as the ordinary scar formation in the common duct. The distribution of these fibers is such that an uncomplicated picture will only be present early in the cases, before there is an associated pancreatitis. Thus, in the more chronic cases, only a careful clinical history and tracing of the course and distribution of the pain will help to locate its original site.

Plexus Mesentericus Superior (figs. 1 23, 2 13 and 4 14).—This plexus forms a shell around the superior mesenteric artery. All the fibers arise from the celiac plexus (ganglions and linking fibers). The vast majority of the fibers run with the superior mesenteric artery to the intestines. Individual fibers run to the hepatic, cardiac, renal, pancreatic and duodenal plexuses.

Plexus Pancreaticus (figs. 1 21, 2 16, 3 10 and 4 11).—This rich plexus is not even mentioned in most textbooks and has never been illustrated. The plexus is made up of two parts. One part supplies the head of the pancreas, the other part the body of the pancreas. The part that supplies the head of the pancreas (figs. 2 16, 3 10 and 4 11) arises with many trunks from the celiac plexus (ganglions and connecting fibers) and from the superior mesenteric, aortic, hepatic and duodenal plexuses. The main part of the plexus lies behind the head of the pancreas and sends fibers from there into the head of the pancreas.

The other portion of the plexus, which goes to the body of the pancreas (fig. 1 21), arises from the splenic plexus, and its fibers enter, one after the other, the substance of the pancreas. Both portions are without macroscopic ganglions.

This distribution of nerves to the pancreas, through its substance and thence to the concavity of the duodenum, explains clearly why acute pancreatitis often simulates ileus and why the latter may be an associated observation. We have seen that in certain cases these nerves may be involved by scar, which may spread between the nerve fibers or even produce amputation neuromas. We suggest the foregoing possibilities

merely as some of the causes of pain in chronic pancreatitis. The celiac plexus may itself be involved by some inflammatory process or through pressure. The former also serves to explain certain types of pain that persist after operations on the biliary system. Pain in pancreatic conditions, particularly cysts, may be due to a "neuralgia" of the pancreatic and celiac plexuses. It may, on the other hand, be due to direct pressure

Fig. 5.—Hepatic, cardiac and duodenal plexus, anterior view. 1 indicates cardiac plexus; 2, caudate lobe of liver; 3, liver; 4, hepatic plexus; 5, right branch of hepatic artery; 6, gastroduodenal artery; 7 and 9, duodenal plexus; 8, duodenum; 10, stomach; 11, left gastric artery, and 12, pancreas.

on nerve endings rather than to pressure and pull on the intestine. Of pain that is pancreatic in origin, it can usually be said that the localization corresponds to the organ from which it emanated. The retroperitoneal position of the pancreas and of important nerve fibers explains, as we

have already mentioned, why there is pain in the back and why pancreatic pain is often increased when the patient is in the dorsal position. It seems that conditions of the pancreas limited to the head of the pancreas cause pain more frequently than those situated elsewhere in the pancreas. The relationship of the common bile duct and the presence of a separate plexus going to the head of the pancreas may perhaps explain this observation.

Plexus Duodenalis (figs. 2 14, 4 13 and 13a and 5 9).—This plexus is not mentioned or illustrated in atlases or textbooks. The plexus lies behind the pancreas on the posterior abdominal wall in the retroperitoneal tissue. The fibers arise from the pancreatic plexus and from the superior mesenteric plexus; a separate portion from the celiac plexus goes to the duodenal jejunal flexure. The branches reach the duodenum on its concavity. The plexus is without macroscopic ganglions. The distribution and arrangement of nerve fibers going to the duodenum suggest a route by which duodenal conditions may be reflected in the pancreas.

Plexus Mesentericus Inferior (fig. 1 10a).—This plexus arises from the aortic plexus and surrounds the artery that bears its name.

Plexus Spermaticus and Ovaricus (not illustrated).—The fine trunks of this plexus arise from the aortic and renal plexuses. The plexuses run with the similarly named artery.

THE MICROSCOPIC STRUCTURE OF THE CELIAC PLEXUS

The trunks of the splanchnic nerves and vagi bring three different morphologic kinds of fibers to the celiac plexus. The nonmedullated sympathetic fibers preponderate in the splanchnic nerves (fig. 6 2). Among these are mixed many thin medullated fibers (fig. 6 1) and also solitary, thick medullated fibers (fig. 6 4). In the abdominal part of the vagus, we found the same three kinds of fibers (fig. 7).

Kiss and Mihálik¹⁴ (1928) showed that the sensory and parasympathetic (vagus) fibers have thin medullary sheaths, that the motor fibers have thick medullary sheaths and that the sympathetic fibers are nonmedullated. These authors also found fibers with thick medullary sheaths in the posterior spinal roots, the function of which is unknown. On the basis of these and the aforementioned investigations, the thin medullated fibers in the splanchnic nerve are known to be sensory, whereas the thin medullated fibers in the vagus are parasympathetic, and the large solitary medullated fibers of the splanchnic nerves probably belong to those leaving the spinal cord through the posterior roots and probably conduct themselves centripetally. The most important fact which the surgeon has to know is that the sensory fibers to the celiac plexus run in the splanchnic nerves; that is why so many thin medullated

Fig. 6.—Transverse section of the nervus splanchnicus major sinister of an adult (osmic acid). 1 indicates thin medullated fibers; 2, unmyelinated (sympathetic) fibers; 3, capillary, and 4, thick medullated fibers.

Fig. 7.—Transverse section of the abdominal portion of the left vagus nerve of an adult (osmic acid). 1 indicates unmyelinated (sympathetic) fibers; 2, thin medullated fibers; 3, thick medullated fibers, and 4, perineurium.

fibers are found in them. It follows from these observations that one finds in the branches of the celiac plexus the same three types of fibers that occur in the splanchnic nerves and in the vagi. In some plexuses, for example, the hepatic and renal plexuses, one finds fewer medullated fibers than one does in the branches of the superior and inferior mesenteric plexuses.

SUMMARY

A description of the celiac plexus from the standpoint of modern surgery is presented.

The celiac ganglions, the roots of the celiac ganglions, the branches of the celiac ganglions and the microscopic structure of the celiac plexus are discussed.

The plexuses of nerves going to the various abdominal organs are also mentioned. Particular attention is drawn to the descriptions and illustrations of the pancreatic and duodenal plexuses. These plexuses have never been illustrated before.

A block anesthesia of the splanchnic nerves gives the same results as infiltration of the celiac ganglions with their uniting branches.

In complete anesthesia of the splanchnic nerves or of the celiac plexus, the sensory, sympathetic and parasympathetic fibers are all blocked.

In order to obtain complete anesthesia, injections must be made on both sides of the splanchnic nerves, or in the celiac ganglions. A single injection suffices, because the splanchnic nerves, as well as the celiac ganglions, lie in loose retroperitoneal tissue.

We have drawn attention to the rich hepatic and pancreatic plexuses, which lie in the field of so many surgical procedures. Important fibers may thus be easily damaged.

It follows from the intimate relationship of the various plexuses with one another and with the centrally placed celiac plexus that certain lesions involving individual plexuses, such as the hepatic or the pancreatic plexus, may have their signs and symptoms reflected in other organs. Some disturbances referable to the duodenum and the pancreas after operations on the gallbladder may be explained on this basis.

THE BRANCHIAL APPARATUS

ITS EMBRYOLOGIC ORIGIN AND THE PATHOLOGIC CHANGES TO
WHICH IT GIVES RISE, WITH PRESENTATION OF A
FAMILIAL GROUP OF FISTULAS *

OLAN R. HYNDMAN, M.D.

AND

GEORGE LIGHT, M.D.

IOWA CITY

Little has been written in this country concerning branchial cleft cysts and fistulas. Phases and fragments of the subject have been discussed in a few worthy papers. The interest aroused in a familial group of branchial fistulas recently studied in this hospital led us to feel that it would be worth while to present a fairly complete and comprehensive review of the whole subject in one paper.

Ninety case reports were studied, as well as the seventeen in our own archives. Many other case reports were not listed because of their incompleteness and because they presented nothing new.

Much of the information concerning the history of this subject was obtained from Wenglowski's extensive work.

HISTORY OF THE SUBJECT

The study of fistulas of the neck up to the presentation of von Ascherson in 1832 was in its infancy and in a chaotic state. After compiling his cases of lateral fistulas with all the known cases of fistulas and cysts at that time, von Ascherson concluded that these fistulas resulted from malformed branchial clefts which failed to close or to unite normally.

In view of the work of von Rathke, von Ascherson was cognizant of a prominent process that developed out of the second branchial arch in vertebrate embryos and that is the most prominent portion of the branchial apparatus; that is, the "Operculum branchiale of Rathke." Ascherson stated that the external orifices of fistulas pointed up under the operculum and thus the fistula was formed by a failure of the cleft boundaries to fuse or close. Succeeding authors, though they believed in the branchial cleft origin of the anomaly, opposed von Ascherson somewhat by introducing the conception that a fistula could develop from any of the four clefts. The fact that prompted this deduction was the

* Submitted for publication, Jan. 24, 1929.

* From the Departments of Surgery and Oto-Laryngology of the University Hospital.

variety of positions that the external orifice might and did take, being limited, as they knew, only by the region of the styloid process and sternoclavicular junction.

According to von Heusinger, the internal orifice of all fistulas was situated at the lateral wall of the pharynx at the base of the tongue. He also believed that the location of the external orifice determined which cleft was at fault, and stated that the fourth cleft was responsible in a case in which the orifice was at the sternoclavicular junction, because by dissection he had found that it coursed along the medial edge of the sternocleidomastoid muscle to the upper border of the larynx and then made a sharp turn toward the midline, opening at the root of the tongue.

Bland-Sutton and von Cussett devised schemas according to which one could determine from which of the four clefts a fistula developed. His doubted the truth and value of these schemas and maintained that the existence of a fistula pointing into the sinus praecervicalis but not into the pharynx is normal in the five weeks' embryo. Later the thymus develops from a portion of the sinus praecervicalis forming a connection between the two. If, he stated, the existing fistula does not grow downward in the thymus region but grows upward, then a true pathologic fistula exists. His, in 1889, changed his mind and stated that the thymus developed from the pharyngeal pouch and not from the precervical sinus.

Rabl refuted His, saying that the fourth cleft could not be a factor in the formation of fistula, because it is separated from the sinus praecervicalis by a thick mesodermal layer. The fistula could not result from the third because it is concerned with the formation of the thymus and therefore the fistula would have to be in close relation with the thymus, which is not true. He paid special attention to the origin of the viscera or organs of the neck from the second arch, since this arch is larger than the others. The second groove consists of a long irregular passage in which two rows of closely opposed epithelial cells divide the pharynx from the outside. He termed this the branchial canal and believed it to be the basis of the formation of fistula only, of course, when the epithelial membrane ruptures and therefore allows communication of the pharynx with the sinus praecervicalis.

In 1890, Kostaniecki and Milecki studied the literature in detail paying special attention to Rabl's work. They did not agree with the schemas of Heusinger, Bland-Sutton, etc., for the external opening of the fistula may at one time be high up near the jaw, then may close and open later in a lower position, and they therefore thought it foolish to say that the position of this opening had such significance as was claimed. The inner opening into the pharynx, however, is constant for any particular cleft or groove. The most frequent and constant internal opening is located in the suprathonsillar fossa, and they concluded from a search of the literature that this corresponded with the second arch.

thus agreeing with Rabl. According to these two men, no branchial cleft could persist in toto, nor could in itself be the cause of a fistula. In the case of the complete fistula, the limiting membrane must be ruptured, and in this way the pharyngeal pouch must first break into the cervical sinus. Thus the complete fistula originates from a rupture of the second pharyngeal pouch into the cervical sinus.

Although later work was based on the observations of these authors, yet some persisted in believing that the first, third or fourth grooves were occasionally the origin of cysts and fistulas. Kostaniecki and Milecki believed that Virchow's case in 1865 originated from the first because of certain coexisting anomalies of the ear.

They, however, denied the validity of Watson's argument concerning a case in which the fistula followed the course of and ran in the stylopharyngeus muscles. That is, he concluded that since the stylopharyngeus muscle originates from the third arch, the fistula must have originated from the third cleft. The refutation was based on the fact that the musculature develops at too late a period to be of significance in this way.

Wenglowski held that if the lateral fistulas belong to the second groove, then the inner openings must be within the limits of this groove or cleft, that is, the arcus palatoglossus muscle (anterior border) and the arcus palatopharyngeus (posterior border). Never, he added, has an inner opening of a fistula been found within the tonsil or between the two limits mentioned. In the cases of Kostaniecki and Milecki, Koztowski, Kotalicki, Neuhöfer, Mobitz, Watson, Rehn, etc., the inner opening pointed at the root of the tongue (unterhalb) in the tonsil fossa and behind the arcus palatoglossus. The inner openings of the lateral fistulas, therefore, since the arcus palatoglossus is formed by a deeply embedded muscle belonging to the third arch, are closely related with the third and not the second arch.

Kostaniecki and Milecki and their advocates argued that the outer opening may be found anywhere and was of no import as regards the origin of the fistula—that the outer opening developed from the inflammation, suppuration and consequent rupture of the inflammatory mass, and the rupture might be at any height or position, depending on the depth or extension of the suppurating cyst or fistula.

Again, to the contrary, Wenglowski stated that after studying a series of cases, one becomes cognizant of the fact that the external openings point in a definite place as a rule. That is, they occur along a line extending from the angle of the mandible to the middle of the sternum, along the medial border of the sternocleidomastoid muscle. If suppuration and inflammation were factors in determining the orifice, it would be only logical to expect it to point anywhere and not follow a definite course as we know it does. That is, they could open lateral to the sternocleidomastoid muscle into it or even into the pharynx and esopha-

gus. In further opposition to Kostaniecki and Milecki, Wenglowski contended that the branchial apparatus does not spread itself into the viscera of the neck but belongs to the head. The second, third and fourth branchial arches do not extend downward but backward or posteriorly. It is self-evident that the branchial arches, as well as the grooves, are definitely and precisely fixed anatomically and topographically. If the formation of the fistula were due to the branchial clefts remaining open, then the fistula would have to open in the region of the submaxillary angle and there would be no basis for its opening lower in the neck. Then again some cases are found in which the external opening is located at the medial edge of the sternocleidomastoid muscle and in exploring the canal one finds that it does not lead upward but downward to the sternum, where it ends blindly. These cases, he contended, cannot have any connection with the branchial apparatus.

History with Special Reference to the Development of the Branchial Apparatus.—The first accurate embryologic description of the branchial apparatus in vertebrates was given by Rathke, in 1825. He described the arches and clefts in the three weeks' embryo of a pig and compared them with the branchial apparatus of the shark.

In 1827, von Baer described four clefts in the human embryo.

In 1832, von Ascherson for the first time discussed the origin of fistulas of the neck from the branchial apparatus, while in 1877, von Cusset made a compilation of various pathologic conditions of the neck independent of the branchial apparatus. He claimed that in man the first arch develops on the fifteenth day and the fourth during the first half of the second month. All arches extend to fuse with their fellows of the opposite side. Their substance consists of embryonic tissue lined externally with flat and internally with cylindrical epithelium. All arches arise in the region of the base of the skull, but because of the rapid growth of the first the lower four are crowded caudally. The rims or borders of all four grooves or furrows are definitely delineated at first but soon fuse, and fuse on the outside first because they grow more rapidly here. If the epithelium does not disappear before this fusion, many pathologic conditions result. The opposing surfaces of all the clefts fuse before the end of two months.

In 1881, His, studying exclusively human embryos and applying the reconstruction method, changed considerably the study of embryology. He found that the endodermal and ectodermal layers came in close apposition with at least only a very small amount of mesoderm or partition between the pharynx and the outside in the region of the clefts. It is not risking too much, he stated, to suppose that this membrane might tear, though, of course, this is not the rule. As one goes caudalward, the distance between the anterior ends of the arches becomes greater

so that at one time a triangular area is formed with its apex upward and was termed by His the mesobranchial field. During further growth, the arches telescope themselves from above down so that looking from the outside, the fourth is covered by the third and the third by the second. In this way, the third and fourth become encased in a cavity in the wall of the neck by the down growth of the second arch. This cavity His called the precervical sinus.

Von Mall (1887) agreed with His and Born. He found that in birds and higher vertebrates no breaking through of the branchial clefts took place, and that these clefts are always separated by a membrane composed of two epithelial layers. In view of the fact that these membranes are thin and delicate, it is possible, he stated, that they could rupture in the living embryo and thus give rise to many anomalies.

In 1888, Piersol came forth with his study of rabbit embryos. He came to the conclusion that the inner pharyngeal pouches are developed earlier and mature later than the outer arches and clefts. In mammals, the rule is, according to him, that the branchial clefts and pharyngeal pouches are separated by limiting membranes and that a tear can take place only in the second. In the first three pharyngeal pouches, two parts can be distinguished, the ventral horn and the posterior extremity, while, in the fourth, the parts cannot be differentiated. Out of the ventral horns, with the exception of the first, the tubular epithelial formations grow.

Foll, von Liessner, Kotschenke, Zimmerman, etc., took a stand opposite to that of His.

In 1884, Foll stated, after studying a 5-6 mm. human embryo, that the branchial clefts must be considered as continuous structures, even though delicate limiting membranes are interposed.

In 1889, von Liessner (studying chick and sheep embryos), concluded that patency of the branchial clefts does exist in all animals with certainty.

Hammer stated that in the 5 mm. embryo, the pharyngeal pouches are well developed and the second is perforated bilaterally at its base.

In summary, therefore, the prevailing theories concerning the origin of the so-called anomalies of the branchial cleft are:

1. The branchial clefts are responsible for cysts and fistulas. (a) A fistulous opening or rest may persist from any of the four clefts (von Heusinger, Bland-Sutton, von Cusset, His, etc.). (b) Only the second cleft can be at fault (Rabl, etc.). (c) The cervical sinus is responsible for the external aspect of the anomaly (von Ascherson, Kostaniecki, Milecki, His, etc.).

2. The thymic stalk and not only the clefts is responsible for their origin (Wenglowski).

EMBRYOLOGY

Early in the life of the embryo (within the first three weeks of intra-uterine life), five bars are prominent in the region of the neck (figs. 1 and 2). These bars are spoken of as branchial arches and the depressions or slits between them as branchial grooves. Within the pharynx (fig. 3) there is a bar and groove opposite each external bar and groove. These structures are covered by ectoderm externally, endoderm internally and contain mesoderm between the two. The mesoderm between the external and internal grooves is absent or nearly so, so that the ectoderm and entoderm are practically adjacent, the membrane so formed

Fig. 1.—A 6.5 mm. embryo. *A* indicates lower extremity, *B* the tail, *C* the umbilical stalk, *D* the nose, *E* the eye, *F* the lower portion of the first branchial arch, *G* the second arch, *H* the third arch, *I* the heart and *K* the upper extremity. (From Wengłowski.)

in the first groove persisting to give rise to the tympanic membrane. These branchial arches and grooves are the forerunners of the gill bars and gill slits, respectively, in fishes, the adjacent ectoderm and entoderm in the depths of the groove having been absorbed to allow the pharynx to communicate with the outside. Hence the derivation of the word branchial (*βραγχια*; gills), meaning pertaining to or resembling the gills of a fish. In mammals, the branchial bars are the anlagen of definite and important structures of the face and neck. Though the grooves normally disappear, except the first, which becomes the external auditory

meatus and eustachian canal, they, by their embryologic nature, not altogether uncommonly persist by failure to occlude or by inclusion of epithelial and endothelial remnants and lay the foundation of the most interesting curiosities and pathologic problems that one encounters in the neck. It is, of course, with the latter that one wishes ultimately to deal, but they are often so complex that some knowledge of their embryologic development and relations is indispensable if one is to have accurate judgment in diagnosis and assurance in treatment.

Fig. 2.—A 6.5 mm. embryo. *A* indicates the branchial groove, *B* the mandibular portion of the first arch, *C* and *D* the nasofrontal process, *E* the eye, *F* the maxillary division of the second arch, *G* the second arch (operculum) and *H* the third arch (operculum). (From Wengłowski.)

The Arches.—The first arch is larger and grows more rapidly than the others, greatly deepening the oral fossa. It early divides into two portions. An upper, the maxillary, portion gives rise to the upper jaw, the lateral parts of the upper lip and the cheeks. The lower portion gives rise to the lower jaw, lower lip and region of the chin. This arch, as do the remaining arches, contains a rod of cartilage, which in this particular arch is known as Meckel's cartilage (figs. 3 and 7). This

cartilage extends from the symphysis menti to the tympanic cavity and lays the foundation of that part of the mandible which develops as intra-cartilaginous bone and which carries the incisor teeth (the remainder being intramembranous bone), the sphenomandibular ligament and two ossicles (malleus and incus).

Both ends of the rod of cartilage in the second arch ossify, the anterior end becoming the lesser cornu of the hyoid bone and the posterior end the styloid process, which fuses with the temporal bone. The intervening portion persists as the stylohyoid ligament.

That portion of the stapes other than the base is probably derived from a portion of the cartilage of the second arch, though its base develops as intramembranous bone. The portion of cartilage in the third arch becomes the greater horn of the hyoid bone, that from the two

Fig. 3.—A diagram to illustrate the branchial arches and grooves. *A* shows the cartilage, artery and nerve contained in the arch.

sides fusing through the body, which also develops from the third arch, and the whole fusing with the lesser cornua, later to form one piece.

The cartilage in the anterior portions of the fourth and fifth arches goes to make up the skeletal elements of the larynx and though it is thought that the greater part, at least, of the thyroid cartilage is developed from the fourth arch, the derivation of the remaining structures is not certain.

In addition to the structures mentioned, which are derived from the cartilage bars of the arches, one must consider the vascular, nervous and muscular content and also the epithelial bodies of the neck to which the arches give origin.

Vascular Content: One recalls that in the human embryo, six aortic arches appear on either side of the pharynx (fig. 4), taking their origin from the ventral aortic trunk and roots, coursing through the branchial arches and joining posteriorly the dorsal aortic roots. In the fishes and

larval amphibians, in which the arches and grooves develop into the gill bars and clefts, these aortic arches persist and develop into a ramifying network of small capillaries in the gill bars, which, when bathed by water circulating through the clefts, absorb its dissolved oxygen.

In mammals, however, marked changes occur early in embryonic life. The first two arches disappear completely (fig. 5), though the origin of the facial artery marks the anterior end of the first arch and the origin of the lingual marks the anterior end of the second. The third becomes the proximal portion of the internal carotid, the distal portion of the internal carotid being the cephalic remainder of the dorsal

Fig. 4.—A diagram of the aortic arches of a mammal. *var* indicates the ventral aortic roots, *vat* the ventral aortic trunk, *dar* the dorsal aortic roots, *sa* the subclavian arteries and *A* the aorta. (From Bailey and Miller.)

aortic root from the junction of the third arch on. The fourth arch on the right and part of that dorsal aortic root becomes the right subclavian, while on the left the fourth arch remains as the arch of the aorta. The fifth and sixth arches disappear, with the reservation that the sixth on the left leading from the pulmonary artery (which has now been separated from the ventral aortic trunk by the septum aorticum) to the descending aorta persists for awhile as the ductus arteriosus (Botalli) and is the future ligamentum arteriosum. We will only mention here and refer to the fact in more detail later that a persistent second groove or remnant of the same would have to course superior to the internal

carotid and that from a third groove would have to course inferior to that artery. It is a well known fact that those fistulas the internal orifices of which are in the suprtonsillar fossa and many branchial cysts lie in the fork of the internal and external carotids.

Nervous Content: The nerve of the first arch is the third division of the fifth (mandibular), while the second contains two, the facial (seventh) and the auditory (eighth). The third arch contains the glossopharyngeal (ninth), the fourth arch the superior laryngeal branch of the vagus and the fifth the inferior laryngeal.

Fig. 5.—A diagram representing the changes in the aortic arches of a mammal. *I C* indicates the internal carotids, *E C* the external carotids, *C C* the common carotids, *I a* the innominate artery, *A a* the aortic arch, *P a* the pulmonary artery, *S a rt* the right subclavian, *S a lft* the left subclavian and *A* the aorta. (From Bailey and Miller.)

It is interesting to note in passing that, since the recurrent laryngeal is laid down anterior to the fourth arch, its forced migration caudalward by the subclavian on the right and the arch of the aorta on the left is accounted for.

Muscular Content: In view of the extensive and remote migration of the muscles about the face and neck, the problem of deducing their exact origin would be complex were it not for the fact that the nerves they carry with them serve as a key. Therefore, the muscles derived from the first arch (i.e., those innervated by the mandibular nerve) are

the muscles of mastication, the mylohyoid, anterior belly of the digastric, the tensor palati and tensor tympani. Those from the second arch (facial) are the stapedius, stylohyoid, posterior belly of the digastric, the platysma myoides and all the muscles of facial expression. Those of the third arch (ninth) are the stylopharyngeus and some of the soft palate muscles. The fourth (superior laryngeal) gives rise to some of the soft palate muscles, the constrictors of the pharynx and the cricothyroid, while the fifth (inferior laryngeal) is the origin of the intrinsic muscles of the larynx.

From the foregoing considerations one is able, if one assumes that either the second, third or fourth groove persists, to deduce the theoretical course of such a resulting fistula or cyst developing from the included rests. In the case of the second, it should pass between the external and internal carotid arteries and superior to the ninth nerve. The third should pass inferior to the internal carotid, lateral to the common carotid, inferior to the ninth and superior to the superior laryn-

Fig. 6.—A diagram to illustrate the enclosure of the precervical sinus (*P S*). *T* indicates the tuberculum impar and *E* the epiglottis.

geal nerves. The fourth should course below the subclavian nerve on the right and the arch of the aorta on the left.

As a matter of fact, the situation is not quite this simple, for at about the fourth week of intra-uterine life the second arch grows outward and downward to meet the body wall, thereby enclosing the external aspect of the second, third and fourth grooves (fig. 6). The ectoderm lined pocket so formed is known as the cervical sinus and is probably responsible in diverse ways for the congenital anomalies. Thus, any of the following mechanisms might possibly obtain: 1. Any one of the grooves might remain as a fistula or a tract of included ectoderm and entoderm in pure form, having its origin and termination in its own normal embryologic location. 2. Any one of the grooves might persist with its normal embryologic origin on the pharyngeal side and by continuation in the cervical sinus have its external opening anywhere from the tip of the styloid process to the sternoclavicular joint. This might explain the fact that the internal orifice of a branchial fistula is almost always in the supratonsillar fossa (and, as will be seen later, undoubtedly originates

in the second groove), though its external orifice varies between the limits described. 3. Any groove might persist in whole or in part and connect with another groove through the cervical sinus.

Epithelial Bodies Derived from the Arches.—Tonsils: The tonsils (third month) arise in the region of the ventral part of the second inner branchial groove, are therefore entodermal in origin and grow as hollow buds into the mesenchymal tissue. Hollowed buds join the main bud, lymphoid cells wander in and by the third month after birth distinct lymph follicles with germinal centers are present.

Thymus: From the ventral part of the third branchial groove on each side (in the 6 mm. embryo), an entodermal evagination appears.

Fig. 7.—A diagram to illustrate the derivatives of the branchial arches. Complete black indicates the first arch (Meckel's cartilage), stipple the second arch, single cross hatch the third arch and double cross hatch the fourth and fifth arches.

This soon severs connection with its parent epithelium and grows caudalward as the thymic stalk, being ventral to the carotid arteries in the 16 mm. embryo and resting on the cephalic surface of the pericardium in the 29 mm. embryo, in which further differentiation of the bilobed thymus is carried out (fig. 8).

Thyroid Gland: In the 3-5 mm. embryo, at the point where the tuberculum impar and the two paired anlagen of the tongue join, there occurs an evagination of pharyngeal entoderm. From this, the site of the future foramen-caecum linguae, the mass of epithelium grows caudalward along the ventral surface of the larynx, giving rise to the thyroid duct. The terminal portion enlarges into the two lateral lobes remaining

connected by the isthmus, while the pyramidal process is a secondary growth from the isthmus, lateral lobes or distal thyroglossal duct.

CLASSIFICATION

It is obvious at once that branchial cysts may be classified from several points of view.

As to Position.—1. Branchial cysts may be superficial or deep (Bailey's classification). 2. They may be auricular or auditory, parotid, submaxillary, sublingual, pharyngeal or tracheal. This classification as to anatomic position alone not only is insufficient but fails to indicate the origin of the cyst, which is important.

Fig. 8.—A diagram showing the branchial derivatives of a rabbit embryo of 16 mm. *T d* indicates the thyroglossal duct, *P* the parathyroids, *P b* the post-branchial bodies, *Th* the thyroid, *C a* the carotid arteries, *T* the thymus and *A* the aorta. (From Bailey and Miller.)

As to Cleft Giving Origin.—This classification is of little value, for it is a greatly disputed point whether more than one cleft is ever responsible for these congenital anomalies. Furthermore, in the case of cysts, it is often difficult to know which groove was responsible for its origin.

As to Contents.—1. Some branchial cysts are mucous cysts. These are usually the deep ones, lined by entodermal epithelium. Many of the so-called ranular cysts belong to this group, including the hour glass cyst of Roser and the congenital mucous cyst in the region of the base of the tongue and the sides of the larynx. 2. Some branchial cysts are atheromatous. These, at first having the appearance of dermoid cysts, are found to contain grumous material, which is entirely desquamated

epithelium without the elements of further differentiation, that is, hair, sweat glands, etc. 3. Other branchial cysts are serous. These have been known as "hydrocele colli" (Mannoir), "congenital hygroma of the neck" (Wernher), "congenital hydrocele of the neck" and "congenital cystic tumor of the neck" (Thomas Smith). These tumors appear as simple cysts lined with pavement epithelium and contain a limpid watery or tenacious fluid holding in suspension epithelial cells and cholesterol crystals.

Hematocysts of Branchial Clefts.—Of these there are two kinds: (1) those which are in communication with vessels and which can be emptied by pressure, and (2) those which are truly simple serous cysts with an admixture of blood, probably from minute hemorrhages in the wall of the cyst. These have been termed "haematocele colli" by Michaux. Senn mentioned that there might also be a true venous cyst in this location resulting from either a segment of vein completely constricted off at both ends or a saccular dilatation which has been constricted at its neck. Such a cyst, though in the region of the saphenous vein, was described by Paget in 1853.

Type of Lining Epithelium.—Lastly, branchial cysts may be classified according to the type of epithelium lining the wall and hence would resolve themselves into: (1) branchial cleft cysts with cylindrical epithelium, or branchial cleft mucous cysts; (2) branchial cleft cysts with pavement epithelium, or branchial cleft epidermoid cysts.

It seems that the latter classification by taking into full account their origin is by far the better.

FAMILIAL AND HEREDITARY TENDENCY

Though there are no reports on which to base an assertion of a hereditary tendency to branchial cysts, there have been several instances of such a tendency to fistulas. The following are reported in Virchow's archives (1861): mother and eight children; mother and son in three instances; mother and daughter; two sisters, a brother and a maternal grandmother; aunts in two instances.

In the familial instance we are reporting, a mother and three of her five children presented fistulas, but she is aware of no similar defect in other members of her family. Thus far, therefore, branchial fistulas may be familial and hereditary, and seem to be inherited only from the mother. No instances, so far as we know, have been reported of inheritance from the father.

CLINICAL FEATURES

This description of the clinical facts was drawn from a study of ninety cases taken from the literature and eighteen additional cases taken

from the archives of this hospital. An outline of the main facts brought out in these case reports is given at the end.

Cysts.—The average age of the persons in whom the ninety cases occurred was about 21 years; the oldest was 48 and the youngest 3 weeks at the time the patients were seen in the clinic. If, however, the average duration of the development of the cyst, which is about four years, is subtracted from these ages, the average age at onset of the cyst is 17 years. This applies only to those appearing some time after birth. In nine patients of this series (21 per cent), the cyst was present at birth. Though fistulas are not infrequently bilateral, we have found no report of a bilateral branchial cyst.

The patient comes to the clinic usually because of a painless swelling in the neck. Owing to its painless nature, the cyst often reaches the size of a hen's egg or lemon before it seriously attracts the patient's attention. In a small percentage of cases, however, the patient complains of pain (as in Thomson's¹ case, no. 29 in the accompanying table), particularly when the cyst swells and becomes tense. In respect to the swelling, many of the patients give a history of fluctuation in size. The cyst is often noted as becoming larger and more tense during the process of salivation, and indeed, as will be referred to later, Coplin² stated that in the case of branchial fistulas, stimulation of salivary secretion by citric acid or mastication usually stimulates secretion from the sinus even when it does not communicate with the alimentary canal. Though the cyst most frequently has an inconspicuous and insidious beginning, occasionally the patient traces it to some shock or injury, as in Jefferson's³ case (no. 9) and as in Glover's⁴ case (no. 27) of a patient who traced a slight swelling on the left side of the neck to an injury received while lifting heavy pipe in the oil fields. There was pain in his neck and it was stiff and sore for several days. He thought he had ruptured a muscle.

Though it is more frequent for the incomplete fistulas opening internally to give their first trouble after tonsillectomy, yet occasionally a deep cyst opening through a fistula internally will be brought to light through inflammation, suppuration or continued drainage after a tonsillectomy (Johnson,⁵ case 3). Not infrequently does a cyst in conjunction with a fistula opening either externally or internally break through and drain copiously from time to time, obviously being of considerable annoyance. In one instance, the material issuing from an inner orifice was of foul

odor. Altogether too frequently to speak well of diagnostic acumen, the patient relates that the swelling has been aspirated many times (from four to fifteen times),⁶ and occasionally incised and drained only to have it return again in every case. Such a procedure always sooner or later introduces infection. With the varying degrees of subsequent reaction, from mild inflammation to suppuration, the latter frequently with poor drainage, the lesion gives rise to pain and establishes a focus of pus and of toxins, which debilitate the victim greatly and cause a loss in weight. The inflammation also renders the wall of the cyst adherent to the surrounding structures, so that any subsequent attempt at dissection is made extremely difficult (Seed,⁷ case 30). Not infrequently symptoms of pressure on contiguous structures are manifested. For example, Thomson¹ reported a case of cyst (no. 29 in the table), which swelled periodically and was associated with pain in the shoulder, dysphagia, dyspnea and a husky voice, which later advanced to complete aphonia, with fixation of the left vocal cord. These symptoms completely disappeared after extirpation of the cyst.

Though we are now discussing cysts, it is interesting to note Carp's⁸ case of fistula (no. 8) in a boy of 5, who was troubled for two years by a dry, hacking cough, worse at night and when the fistula did not discharge. At operation, the fistulous tract was found to be adherent for a short distance to the vagus. The paroxysms of coughing completely disappeared after the operation. In Smith's⁹ case (no. 43) of fistula in a child of three weeks, respiration and deglutition were markedly impaired. In one of our cases (E. E.), the fistula on the left opened into a cyst the size of which varied from that of a filbert to that of a hen's egg, and the patient would experience, in association with the swelling, nervousness, restlessness, hoarseness and palpitation of the heart. During the first attempt to probe the complete fistula on the right, it seemed that when a certain point was reached and before the probe was through the inner orifice, coughing, uneasiness and distress were stimulated. On the second attempt to probe the tract, sometime later, when we were unsuccessful on account of partial obliteration, the mere introduction of the filiform caused vomitus to well up in the throat.

The right side of the neck was involved in seventeen (35.5 per cent) and the left in twenty-one (64.5 per cent) of the cases. This proportion is about equally true for male and female taken separately.

9. Smith, Thomas: Congenital Cystic Tumor, *St. Bartholomew's Hosp. Rep.* **2**:16, 1866.

On examination, one finds a regular hemispherical tumor, the skin surface over which appears smooth. The size may be from that which is just detectable to that which fills the whole side of the neck. It is often described as being the size of a filbert, a walnut, a hen's egg or an orange, etc. It may be large enough to protrude in the floor of the mouth as in the case reported by Senn¹⁰ (no. 40). Treves¹¹ reported a case in an infant (no. 44), in which the whole side of the neck and the thorax on that side down to the umbilicus was involved. The cyst may be located about the pinna and anywhere from this region to the junction of the sternocleidomastoid and the clavicle, and even may extend somewhat lower than this, so that it is partly substernal, the swelling pointing in the suprasternal notch. Those cysts that are located in the neck bear a definite and constant relation to the sternocleidomastoid muscle. It can be said with impunity that if they are of any considerable size, they extend, at least in part, under this muscle and this is one of the most dependable clinical features of this type of cyst. Submaxillary cysts are, of course, excepted. Frequently the fibers of the muscle will be thinned out owing to long continued pressure from the cyst and one might get the false impression that the muscle belly goes through the tumor. The true relationship in many cases, however, may be easily brought out by merely having the patient attempt to rotate his head while the examiner holds the chin, so as to place the sternocleidomastoid muscle on the stretch, and at the same time palpating it. As the cysts grow larger to accommodate their accumulated secretion and contents, they dissect their way, of course, along the planes of least resistance and the direction that they take depends considerably on the depth of the cyst. In regard to their depth, Bailey⁶ has classified them as (1) those lying just beneath the skin; (2) those extending deeper and attached to the internal jugular; (3) those passing between and straddling the bifurcation of the common carotid, and (4) those of the mucous or columnar cell type lying entirely posterior to the common carotid next to the pharynx. The larger and more superficial ones may extend toward the midline and bring up the question of thyroglossal duct cyst, but they practically always are eccentric enough to preclude being the latter. It seems to have been the rule that the cysts taking origin in the neck may dissect as high as possible under the sternomastoid muscle and therefore behind the ear but seldom dissect over the jaw and anterior to the ear as may hygromas. This point was brought to bear in a recent questionable diagnosis at this hospital.

10. Senn, N.: Branchial Cysts of the Neck, *J. A. M. A.* **3**:197 (Aug. 23) 1884.

11. Dissection of a Congenital Hydrocele of the Neck, *Virchows u. Hirsche Jahresbericht* **1**:280, 1882; quoted by Pranesk.

The uncomplicated cyst is most frequently obviously fluctuant and rather soft, though the so-called atheromatous or dermoid types may be rather firm and nonfluctuant. The latter may be lobulated, rendering their differentiation in diagnosis from tuberculous glands especially difficult. This difficulty is increased if secondary infection has taken place and more especially if there is an externally opening fistula through which the puslike or grumous material periodically escapes. If the latter condition is present, an examination of the fistulous orifice with a hand lens will be enlightening, provided the inflammatory process has not completely destroyed the anatomic definitive. The uncomplicated cyst has been described as having a multilocular feel, but this is not common. Although one cannot get the sensation by feeling through the overlying structure, yet, at operation, when feeling through only the thin wall of the cyst, the sensation one gets is much like that when feeling lung. The cyst wall is not adherent to the overlying structures, but feels to be so deeply, and this assumption is, in most cases, proved to be true at operation. Uncomplicated branchial cysts are not painful, except in rare cases owing to pressure, and are not tender.

Secondary infection, of course, changes the picture completely. All the signs of inflammation obtain, with adherence to the surrounding structures, pain, tenderness, fever, leukocytosis, etc.

Fistula.—In the series of sixty-two cases of branchial fistulas, 53 per cent occurred in females and 47 per cent in males. Fifty-one and eight tenths per cent were on the right side, 31.4 per cent were on the left and 16.8 per cent were bilateral. One interesting case reported in Virchow's archives (1861) presented multiple small openings on the right at the junction of the sternocleidomastoid muscle with the clavicle. This is the only case of multiple unilateral fistulas that we were able to find record of. It may be noted that the right and left incidence here is the reverse of that for cysts.

In the case of fistula, the feature that brings the patient to the hospital is practically always drainage, which may be periodic. It may consist of clear, tenacious mucus (said not to be of the chemical character of saliva) or thin, milky and puslike.

True fistulas practically always exist from birth and may be of such capillary dimensions as often to escape notice. Obviously, the incomplete fistulas that open only internally may never come to attention unless they are large enough to fill with food or unless they become infected and drain habitually, a condition which, as mentioned, is not infrequently initiated by tonsillectomy. A fistula opening into the trachea may give rise to air sacs and present the features of what has been termed "aerial goiter," "aerial bronchocele," "tracheocele" and "hernia of the trachea" (Coplin; ² Eldridge ¹²). Eldridge described such

12. Eldridge, S.: Am. J. M. Sc. 78:70, 1879.

a condition in a patient 26 years of age—an air cyst on each side of the lower part of the pharynx and the upper part of the trachea, which grew larger on expiration and increased the circumference of the neck from 40.5 to 49 cm. The external orifice may be situated about the pinna, or in the neck always just anterior to the sternomastoid muscle.

Often there is a small areola of brownish discoloration about the external orifice and occasionally a small bit of tissue, which is invariably found to contain a piece of cartilage. These are known as "super-numerary" or "cervical auricles."

By picking up the skin about the orifice, one can feel the cordlike tract extending into the neck. By traction, it prevents the orifice from being lifted as high as the surrounding skin.

Mention has been made of such symptoms and signs as pallor, uneasiness, palpitation of the heart, coughing and vomiting on probing the fistula, which can be adequately accounted for by the proximity of a portion of the tract to the vagus.

Among unusual cases that have been reported, the following are of passing interest:

Lesser reported a patient in 1840 (Virchow's archives), who traveled with a show and made his livelihood by passing a curved knitting needle into the pharyngeal orifice of a fistula and extracting it from the external orifice.

Ascherson presented a patient who, though having originally only one external orifice, later developed three, the fistula closing and opening in a new place each time.

Von Berg showed a patient in whom the external opening was in the incisura thyroidea and communicated with the middle ear. When the external orifice closed, material would discharge from the ear, while injections made in the external opening gave rise to pain in the middle ear.

Branchial cleft fistulas have also been described as occurring in cats and dogs.¹³

DIAGNOSIS

In arriving at a diagnosis of branchial cleft cyst, one should have in mind that it is usually a uniform, painless, fluctuant, semifixed, non-translucent tumor with a characteristic relationship to the sternocleidomastoid muscle and without tenderness. The differential diagnosis involves the following:

Adenitis.—Nontuberculous adenitis usually involves more than one gland and not infrequently both sides, and tenderness is the rule. The offending focus may be found in the tonsils or the teeth. Tuberculous

13. Heusinger: Halsfiemenfisteln des Menschen und Thiere, Deutsche Ztschr. f. Thiermed. 2:1, 1876.

adenitis is the most difficult to rule out. Of course, no effort should be spared on behalf of the patient to rule this out, for the stigma of tuberculosis in a young person is of considerable gravity. The fact that aspirated material may resemble tuberculous pus closely and be free from pyogenic organisms tends only to confirm the physician's original diagnosis of tuberculosis, unless he is aware of the possibility of its being a branchial cyst. The likelihood of the lesion's becoming infected and draining for an indefinite period also supports his delusion.

Though the atheromatous branchial cyst filled with grumous cheese-like material is glandular and firm and, if secondarily infected, is adherent to the surrounding structures and tender, yet in tuberculous adenitis it is more frequent to find other swollen glands or a group of matted glands. It is of some diagnostic importance that branchial cysts seem more common in the white race and tuberculous adenitis more common in the colored race. A cyst associated with an external fistula might be deceiving, but, as mentioned, a careful examination of the orifice of the fistula can be enlightening.

Cystic Hygroma.—Translucency is the most important differential feature and can be said itself to be diagnostic.

Thyroglossal Duct Cyst.—Such cuts are practically always in the midline and are so attached to the thyroid gland or trachea that they move forcibly during deglutition. Microscopically, it is frequently impossible to make the distinction.

Venous Hemangiomas.—These growths decrease in size on pressure, though one must be sure the contents of the tumor have not merely been squeezed into another compartment of the same.

Retropharyngeal Abscesses.—Such abscesses are painful and may exhibit swelling and tenderness on only a cursory examination of the pharynx.

Lipomas.—Lipomas, as well as other solid tumors, do not yield fluid material on aspiration.

For diagnosis, the demonstration of cholesterol crystals in the aspirated material of the cyst is helpful, though dermoid cysts produce this substance also.

Fistulas are sometimes injected with colored substances, such as methylene-blue (methylthionine chloride, U. S. P.), which, if the fistulas are complete, will issue from the internal orifice into the mouth. Bismuth paste has been injected and x-ray photographs obtained (cases 28 and 31). They have also been probed with small flexible filiforms, bristles of hair, etc. In one of our cases (fig. 9), we were able completely to pass an x-ray ureteral catheter and obtained roentgenograms, which were studied for the direction and curvature and relation of the tract to the hyoid bone.

PATHIOLOGY

In removing a branchial cyst, one often finds it attached at one pole to a fistulous tract, which most usually extends toward the tonsillar fossa. This tract often diminishes down to such fine caliber that it cannot be completely dissected. The wall of the cyst is usually smooth, though it may vary in thickness from that of tissue paper to 0.25 cm. It has been mentioned that one of these had the feel of lung, which was accounted for probably by numerous interlacing, tough, fibrous strands seen on the inner aspect of the wall, which were at first suspected of being hair.

Grossly, the content of the cyst is usually a thick, transparent, mucoid, sticky substance in those lined by columnar epithelium, while it

Fig. 9.—An x-ray picture of a patient with a ureteral catheter in a fistula. The markers designate the external orifice and the internal orifice in the tonsillar fossa.

is opaque, watery and milky or cheeselike and of all the consistencies between the two in those lined by squamous epithelium. The fluid content often can pass through a hypodermic needle, and though it may bear a striking resemblance to tuberculous pus, if some of it is placed in water, the shimmering lipid substance will be evident floating on the surface.

The cellular content has been found (Coplin²) to be as follows: (1) large cells resembling squamous epithelial cells, 93.7 per cent; (2) polymorphonuclear leukocytes, 1.8 per cent; (3) erythrocytes, 0.5 per cent, and (4) mononuclear leukocytes and unidentified cells, 4 per cent.

Gurlt, quoted by Senn,¹⁰ mentioned a great similarity between the contents of these cysts and the contents of ovarian cysts. He mentioned

the careful chemical examination made by Hoppe, which was as follows: 1.3953 Gm. of atheromatous material contained 0.2225 alcoholic extractive matter, 0.1235 ethereal extractive matter, 0.2005 aqueous extractive matter and 0.8555 insoluble matter. In these substances, he found leucine, tyrosine, cholesterol, myelin, palmitin and stearin.

Histologically, the walls of the cyst present many interesting features. The most usual observation is a well organized, stratified, squamous epithelium resting on a relatively thick band of lymphoid

Fig 10—A photomicrograph of the wall of a branchial cyst to illustrate a stratified epithelium resting on a connective tissue base without the interposition of a band of lymphoid tissue. (Case 51, S. R.)

tissue, while beyond this is connective tissue, which may contain varying amounts of smooth and striated muscle (most likely extracapsular), and which is usually infiltrated to some extent with the elements of chronic inflammation—round cells, mononuclears and an occasional eosinophil leukocyte. The zone of lymphoid tissue may be entirely absent, the epithelium resting immediately on connective tissue (fig. 10). Again, it may be scant or abundant and with distinct and well formed lymph follicles (fig. 11). The epithelial layer, though in most cases

composed of stratified squamous cells, is now and then columnar with or without cilia (fig. 12).

One of our sections exhibited both the stratified and the columnar epithelium, while one showed well formed mucous glands just beneath the squamous epithelium. The differentiation from dermoids and other anomalies of earlier ontogenetic origin and their close simulation of the commoner epidermoids lacking hair, sweat glands,, etc., has been mentioned.

Fig. 11.—A photomicrograph of the wall of a branchial cyst to illustrate a stratified epithelium on a dense lymphoid tissue base. (Case 45, L. P.)

The stratified squamous epithelial layer appears like that of normal skin. There are, however, no papillae, except rudimentary ones, and the various layers are not discernible. The stratum germinativum or rete malpighii may be evident forming a row of cells with their oblong nuclei set perpendicular to the base, often containing considerable pigment and showing, as well as do many of their offspring, definite prickly cell characters. The nuclei are large, well defined and reticulated and contain one or more chromatin masses. They take the hematoxylin stain well and often maintain these characters well out to the stratum

corneum, where they suddenly cornify and are sloughed away. The cytoplasm stains darkly, appears finely granular and in places, owing to the prickled borders, is easily outlined. In some cases, the cells soon lose their original characteristics and become vacuolated long before reaching the stratum corneum. Though it has been mentioned (Coplin²) that the lymphatic layer is not especially vascular, we find the contrary to be true in our sections, many of them showing numerous vessels. It is true, however, that most of these also exhibit the elements of chronic inflammation.

Fig. 12—A photomicrograph of the wall of a cyst to illustrate the ciliated columnar epithelium on a rather dense lymphoid tissue base. (Case 48, N. H.)

There are certain anatomic and histologic features of branchial cysts and fistulas that make their origin solely from branchial clefts more convincing than an origin from thymic stalk, as maintained by Wenglowski.¹⁴ The latter believed that cysts and fistulous tracts lined with stratified squamous epithelium are ectodermal and must undoubtedly be of cervical sinus (Halssinus) origin, while the anomalies

14. Wenglowski, R : Ueber die Halsfisteln und cysten, Arch. f. klin. Chir. 100:789, 1913.

and portions of the anomaly that are entodermal are of thymic stalk origin. He felt that the dense lymphoid tissue with sometimes definite lymphoid follicles and occasionally what appear to be Hassall bodies in the walls of cysts and fistulas is strong evidence of thymic origin. It

Fig. 13.—A photograph (natural size) of an atheromatous branchial cyst removed from the right submaxillary region of V. H. (fig. 14). The cyst has been ruptured exposing the grumous contents of desquamated epithelial cells and cholesterol crystals. The wall was lined with stratified squamous epithelium.

Fig. 14.—Patient V. H. with an atheromatous branchial cyst in the submaxillary region of the right side. A photograph of the gross specimen is shown in figure 13

seems, however, that, in view of the fact that cysts lined wholly by prickle cell stratified epithelium, and therefore of undoubted ectodermal origin, are commonly found exhibiting the dense band of lymphoid

tissue, the latter cannot be used to bear witness of thymic origin. For the thymic anlage cannot have had to do with such a cyst. Further, the cysts located as high as the region of the tip of the mastoid present the same histologic characteristics, and there is certainly no reasonable proximity of such a structure to the region of the assumed remains of the thymic stalk.

Figure 15

Figure 16

Fig. 15—*A* indicates the brain cavity, *E* the eye, *IA1* the superior division of the first branchial arch, *IA2* the inferior division of the first branchial arch, *IIA* the second branchial arch, *IVPC* the fourth pharyngeal cleft, *P* the pharyngeal canal and *N* the neural canal

Fig. 16—*IA1* indicates the superior division of the first branchial arch; *IA2*, the inferior division of the first branchial arch; *IIA*, the second arch; *T*, the thyroid anlage (the thyroglossal duct has disappeared at this state); *IIIA*, the third arch; *IVC*, the fourth cleft and *P*, the pharyngeal canal.

Wenglowski brought out that some of the external fistulas point downward instead of upward. One would expect this occasionally to be true, but so far as we were able to ascertain, no such fistula extended far enough to be convincing in this regard. In patient E. E. (case 58), the filiform, when passed into the left orifice, turned downward

Figure 17

Figure 18

Fig. 17.—*IIA* indicates the second arch; *T*, the thyroid anlage; *IIIA*, the third arch; *IIIPC*, the third pharyngeal cleft; *IVA*, the fourth arch and *IVC*, the fourth cleft. The second arch is seen here to be growing downward to meet the body wall and inclosing the third and fourth arches forming what is known as the cervical sinus (Halssinus).

Fig. 18.—*IIA* indicates the second arch; *IIIPC*, the third pharyngeal cleft, now joining the pharyngeal canal; *IIIA*, the third arch and *IVA*, the fourth arch and cervical sinus shown on the right.

about one-half inch (1.27 cm.), but then turned up suddenly and joined a definite cyst. Also, if the remains of a thymic stalk played a rôle, cystic structures should occur anywhere from the final resting place of the thymus to the region of its origin. Langebeck, quoted by Senn,

Figure 19

Fig. 19.—*RP* indicates Rathke's pouch; *IIPC*, the second pharyngeal cleft and *IIC*, the second cleft.

Figure 20

Fig. 20.—*RP* indicates Rathke's pouch; *P*, the pharyngeal canal; *IIPC*, the second pharyngeal cleft; *IIA*, the second arch and *IIC*, the second cleft.

stated that branchial cysts are frequently attached to the greater horn of the hyoid bone or to the thyrohyoid ligaments, localities that plainly indicate that they originated from remnants of former branchial clefts.

So far as fistulas are concerned, the third groove, being embryologic like the second, would seem to have the same chances of persisting, though so far as the external and complete fistulas are concerned, their tracts are practically always reported as coursing between the external and internal carotid arteries and having exit in the supratonsillar fossa and therefore must be of second groove origin. We are in poor position

Figure 21

Fig. 21.—*RP* indicates Rathke's pouch; *IPC*, the first pharyngeal cleft on its way to meet the first outer cleft shown later, which forms the eustachean tube; *TM*, the tongue mass; *IIPC*, the second pharyngeal cleft.

Figure 22

Fig. 22.—*RP* indicates Rathke's pouch; *IPC*, the first pharyngeal cleft; *TM*, the tongue mass and *IIPC*, the second pharyngeal cleft. The external first clefts are shown on both sides here, which will be met soon by the pharyngeal or internal first clefts. The first external clefts form the external auditory meatus.

to draw conclusions about incomplete internal fistulas. These must be far more common than one suspects, for it is not reasonable to suppose that they would ever be discovered if they remain relatively undisturbing to the patient. It is often extremely difficult to locate the internal orifices.

Figure 23

Fig. 23.—IPC indicates the first pharyngeal cleft and IC, the first (external) cleft. The membrane between IPC and IC forms the tympanic membrane.

Figure 24

Fig. 24.—IPC indicates the first pharyngeal cleft; IC, the first (external) cleft and OV, the otic vesicle.

We have no report of a fistulous tract coursing inferior to the right subclavian artery or aortic arch, and believe, therefore, that the fourth groove is practically never responsible for such structures.

So far as the branchial grooves ever being normally patent is concerned, we find no indication of it in the serial sections of a 7.5 mm. human embryo (figs. 15 to 25). Owing to the manner in which serial sections are cut, one might get the impression of a patency from the pharynx to the outside but on following the true pharyngeal side

Fig 25—OV indicates the otic vesicle

of the groove this is seen not to be the case (i.e., the manner in which the fourth external cleft is cut on the left in figures 15 and 16 and on the right in figures 16 and 17 might be deceiving in this regard).

It seems far fetched to assume a tear of the groove membrane in early embryonic life as the cause of fistulas. In assuming this, one is practically limited to trauma, and it is hard to believe that in so small

an embryo, so well protected, trauma could be of just the extent to establish a fistulous communication between the pharynx and the outside. Even if such an accident occurred, there would be no logical reason for its persistence. Again, it cannot be supposed that cysts, the origin of which must be the same as that of fistulas, are established by tears of the groove membrane in a neck that has never presented the stigmas of external or internal fistulas.

There has been little contributed on the subject of the origin or existence of aural fistulas. The anomaly has usually been lightly passed over with the assumption that it originates in the first branchial groove.

Fig. 26.—Patient E. E. (case 58), with bilateral cervical fistulas and an aural fistula on the left. A urethral filiform is shown entering the external orifice and coming through the mouth having made its exit in the supratonsillar fossa.

It is difficult, however, to attribute it to such an origin when, as is known, the first groove normally persists in the formation of the external auditory meatus and the groove membrane in the formation of the tympanic membrane. It has been also suggested that fistulas, as well as cysts, in this region are the result of epithelial inclusions or of anomalous development of the several tubercles that go to form the pinna. The fistula was blind in all of our familial cases, was only an eighth to a quarter of an inch (from 0.3 cm. to 0.6 cm.) in depth and had never been the site of a discharge.

Histologically, these anomalies present none of the structures of advanced differentiation such as hair follicles or sudoriferous glands, though in one of our sections well formed mucous glands were contained in the cyst wall just beneath the lining epithelium. The explanation of this difference from teratomas and dermoids rests on the fact that the inclusions are made after the three germinal tissues have well differentiated. Branchial cysts are indeed, therefore, not greatly different from any of the commoner epidermoid cysts, i.e., the epidermoid cysts about the face and palms of the hands resulting from epithelial inclusions or bits of epithelium buried by trauma and subsequently continuing their active growth and desquamation. In the latter there is often, too, a marked lymphoid infiltration in the cyst wall, but so far as we know, no well defined lymphoid follicles.

Fig. 27.—Patient E. E., showing symmetry of the cervical fistulas.

TREATMENT

The treatment of branchial cleft cysts and fistulas may be dismissed with one consideration—complete excision of the epithelial wall. This may be simple for superficial cysts, but technically extremely difficult for deep cysts and fistulas. We feel that it is not advisable to inject the cyst with methylene blue at operation owing to the marked disadvantage of having the operative field stained with the dye should the cyst rupture. If the operator is anxious to determine a possible communication with an internally opening fistula, the disadvantage might be obviated by washing the dye out of the cyst, thereby leaving only its wall stained. The relation of branchial anomalies to the vital structures of the neck makes their dissection a tedious one, and it should be attempted only by those who are acquainted with the anatomic minutiae

of the neck; for, obviously, if the dissection is not complete, the technical difficulty of a second operation is increased many-fold.

Most of the commoner corrosive substances have frequently been injected into the cysts, but are invariably without effect.

Fig. 28.—Patient E. E., illustrating the external orifices of symmetrical bilateral cervical fistulas and an aural fistula on the left. The right cervical fistula was complete, while the left led to a cyst, which fluctuated from the size of a filbert to that of a hen's egg.

Figures 15 to 25 were selected from 200 camera lucida drawings prepared by Dr. H. J. Prentiss from serial sections made of a 7.5 mm. human embryo. The sections were 10 microns thick and the drawings

Fig 29—Patient C E, showing a cervical fistula and a probe in the aural fistula on the right.

Fig. 30—Patient W E, showing bilateral cervical fistulas and probes in bilateral aural fistulas.

made from alternate sections. This stage of embryonic life is about the optimum for the illustration of the branchial apparatus. The sections were cut in such a way that the two halves are not symmetrical. Also, it should be remembered that due to the marked flexion of the embryo ventrally, sections taken from ventrum to dorsum will progress caudalward in the head region and cephalicward in the tail region. The sections shown in figures 15 to 25 progress ventrodorsally.

REPORT OF CASES

The following group of cases, which occurred in a mother, two daughters and a son, present familial branchial cleft fistulas:

CASE 1.—E. E., a colored woman, aged 28, entered the hospital with a complaint of frequent sore throat for two or three years past, a lump in the left side of the neck of four years' duration and a discharging sinus on each side of the neck. The family history and the social history were essentially without bearing. She had

Fig. 31.—Patient B. E., showing a cervical fistula and a probe in the aural fistula on the right.

five children, living and well, and had had no miscarriages. She said that she had never had any signs or symptoms of venereal infection. She had noticed the sinuses in the neck from birth, and from time to time (about three or four times a year) had observed that they seemed to swell slightly just at the point of exit and that in a short time they broke down discharging a few drops of whitish, translucent material. She felt that the one on the right opened into the throat, for occasionally a foul tasting substance seemed to be ejected on the right side of the mouth. For the past four years, she had noticed a swelling in the left side of the neck, which varied from the size of a filbert to that of a hen's egg. The fluctuation in the size of this swelling had no relation to mastication. When the mass swelled to its maximal size, she experienced nervousness and palpitation of the heart. There seemed to be also some difficulty in talking; that is, her voice seemed hoarse. In addition to these symptoms, she experienced pain in the region of the left shoulder, which she herself attributed to the lump in the neck because it was present only when this lump was swollen to its maximal size.

Summary of Data in Sixty-One Cases of Branchial Cleft Cysts and Fistulas

Author	Age, Years	Sex	Fistula (Side of Neck Involved)	Cyst (Side of Neck Involved)	Duration	Location in Neck	Hereditary Tendency	Diagnosis	Operation	Result	Remarks	Pathology	
1. Crow, I. N.; J. Iowa M. Soc. 15: 521, 1923	48	W	M	Right	?	Tonsillar fossa	0	Correct	+	Well	Cleared white particles from throat at times; fistula from 2 to 3 cm. in length, emptying into tonsillar fossa	Stratified squamous epithelium; lymphoid near basement membrane
2. Whitacre, H. J.; Ann. Surg. 37: 86, 1903	5	W	F	Right	Since birth	Lower third	0	Correct	+	Well	Began after tonsillectomy....	Stratified squamous epithelium
3. Johnson ^c	24	..	F	Left	1.5 yr.	Middle third	0	Correct	+	Well	Discharging fistula at birth healed after six years; after four years more, became infected; between external and internal carotids	Pus was aspirated at one time, but at operation cyst contained 2 ounces of semigelatinous fluid; stratified squamous epithelium
4. Johnson ^c	14	..	M	Right	Since birth	Lower third	0	Correct	+	Well	Between external and internal carotids; no communication with pharynx	Pear shaped cyst; inner wall smooth and filled with mucus
5. Johnson ^c	17	..	F	Right	Since birth	Lower third	0	Correct	+	Well	Between external and internal carotids; no communication with pharynx	Cyst 5 by 1 cm., lined with stratified epithelium
6. Johnson ^c	21	..	M	Left	Since birth	Lower third	0	Correct	+	Well	Between external and internal carotids; no communication with pharynx; discharged seropurulent material for seven years; healed fourteen years, then broke down	Tract 3 by 1 cm., containing mucoid material; lined by squamous epithelium on lymphoid tissue
7. Johnson ^c	7 mo.	..	M	Left	Since birth	Lower third	0	Correct	0	Well	Had remained closed for one year when last heard from	
8. Carp ^a	5	..	M	Right	Since birth	Lower third	0	Correct	+	Well	Healed from time to time; first discharged at 2 years; paroxysms of coughing ceased after operation; between carotid artery and veins	
9. Jefferson ³	18	..	F	Right	6 wk.	Middle third	0	Correct	+	Well	Supposed to have followed trauma	
10. Jefferson ³	47	..	F	Left	5 yr.	Middle third	0	Correct	+	?	Tender and brawny; pus drained and later cyst excised; between external and internal carotids and connected to pharyngeal wall by stalk	
11. Coplin ²	36	..	F	Right	3 yr.	Upper third	0	Lipoma?	+	Well		Sac 7 cm. in long diameter; squamous epithelium on lymphoid base; contained many one, two and three nucleated epithelial cells and a few polymorphonuclears

No.	Patient	Age	Sex	Side	Duration	Location	Treatment	Result
12.	Bryan, A. D.; S. Clinic, Chicago 4-11, 1920	19	M	Left	2 yr.	Upper third	Correct +	Well
13.	Bailey "....."	17	M	Lower third	2 yr.	Tuberculous + adenitis	? Aspirated seven times; then cyst size of tangerine shelled out
14.	Bailey "	20	F	Left	12 yr.	Tuberculous + adenitis	? Aspirated five times; later, cyst size of egg shelled out
15.	Bailey "	27	F	Lower third	2 yr.	Tuberculous + adenitis	? Aspirated fifteen times; later, cyst size of orange shelled out
16.	Bailey "	35	M	Lower third	18 mo.	Tuberculous + adenitis	? Incised and drained; later, large cyst dissected out
17.	Bailey "	20	F	Lower third	14 mo.	Tuberculous + adenitis	? Aspirated five times; pus sterile; given tuberculin; later, egg-size cyst excised
18.	Bailey "	26	M	Left	14 mo.	Middle third	Tuberculous + adenitis	? Aspirated four times; later, orange-size cyst dissected out
19.	Bailey "	20	F	Right	10 yr. 4 mo.	Middle third	Correct +	? Cyst size of orange

The forty-six cases of branchial cleft fistulas reported in Virebow's Archiv fur pathologische anatomie und Physiologie for 1891 were not included in this table.

On examination, the external fistulas were seen, as shown in the photograph. Aside from a marked hypertrophy of the tonsils and some hypertension, the results of the physical examination were essentially negative. The tonsils were so large that the internal orifices of the fistulas could not be seen until after the probe was passed. A urethral filiform catheter was passed with little difficulty through the right fistula; it emerged in the supratonsillar fossa. The filiform entered the fistula on the left and pointed down about one-half inch (1.27 cm.), then turned abruptly up and entered apparently into a somewhat firm lump on the left side of the neck. The internal orifice was not found on this side. The filiform on the right was followed by an x-ray catheter, after the passage of which stereo x-ray pictures were obtained. After the catheter had been introduced one half to two thirds of the way in the fistula on the right side, uneasiness and coughing were induced. Feeling that the stiff catheter would distort the fistulous tract to some extent, we later decided to inject iodized poppy seed oil 40 per cent. But after two weeks the fistula had become obliterated to such an extent that it was impossible to inject the iodized oil. This patient also had a fistula, just anterior to the left ear, which was about one fourth of an inch deep (0.63 cm.). There was no discharge from the fistula. In fact, it had never been brought to the patient's attention.

CASE 2.—C. E., a colored boy, aged 3, had a fistula on the right side of the neck and a right aural fistula, as shown in figure 29. Otherwise he was normal. The cervical fistula, on pressure, emitted a drop of clear, mucoid, tenacious fluid. The discharge from this fistula to the time of writing had been slight.

CASE 3.—W. E., a colored boy, aged 4 years, 8 months, had bilateral cervical fistulas and bilateral aural fistulas, as shown in figure 30. The results of the physical examination were otherwise negative. One of the cervical fistulas, to the time of writing, had discharged several times without pain or swelling.

CASE 4.—B. E., a colored girl, aged 6 weeks, had cervical fistula and aural fistula on the right (fig. 31). She presented no other abnormalities. On pressure, a small amount of clear, mucoid fluid could be expressed.

The two remaining children did not present branchial anomalies.

CONCLUSIONS

1. Branchial cleft anomalies (cysts and fistulas) result from a failure of absorption of the included ectodermal and entodermal epithelium that is buried during the growth and fusion of the branchial arches in early embryonic life. This is most probably the sole explanation, the thymic stalk playing no rôle.

2. Branchial cysts, in truth, are epidermoid cysts of the neck whose parent epithelium was buried during the development of the branchial apparatus. Their characters are more varied, of course, than those of the commoner epidermoid or inclusion cysts owing to the activity of entodermal or ectodermal epithelium or both. Many of the submaxillary cysts and so-called ranulae are of branchial origin.

3. Branchial fistulas may be familial and hereditary, and they seem to be inherited through the mother only.

4. More attention should be given to the possibility that a tumor in the neck is of branchial origin, especially in view of their frequent simulation of tuberculous glands and their occurrence in early youth. This is enjoined even more by the fact that results from treatment are in proportion to the completeness with which the epithelial wall is excised.

5. An adequate and simple classification of the cysts would be (a) branchial cleft epidermoid cysts and (b) branchial cleft mucous cysts.

LYMPHATIC DRAINAGE FROM THE PERITONEAL CAVITY IN THE DOG *

GEORGE M. HIGGINS, Ph.D.

AND

A. STEPHENS GRAHAM, M.D.

Fellow in Surgery, Division of Experimental Surgery and Pathology,
The Mayo Foundation

ROCHESTER, MINN.

Accurate data concerning the extent and the routes of drainage from the abdominal cavity of patients with gastro-intestinal lesions are of extreme importance. Pulmonary involvement, so commonly associated with abdominal operations, is a sequela which may be explained by the lymphatic continuity of the two regions. Many experiments have been made in an effort to determine the site and rate of absorption from the peritoneal cavity and the routes through which such materials are removed. Cunningham¹ completely reviewed the literature which concerns these various phases of the problem.

In the hitherto published accounts of experimental studies on the method of lymphatic drainage following peritoneal absorption, more careful attention has been given to the cytologic problems than to the lymphatic paths which are involved; also to the manner in which the foreign particles within the peritoneal cavity get into the lymph stream, whether free and independent or in phagocytic cells, than to the distribution of the lymph channels throughout the diaphragm, mediastinum and pulmonary regions. In the process of absorption from the peritoneal cavity, the lymphatic tracts of the diaphragm are most extensively involved. From this muscular partition the lymph may flow either through the anterior mediastinum and its associated lymph nodes or, to a lesser degree, into the thoracic duct and thence to the venous circulation at the jugular subclavian confluence.

Our interest in the problem of peritoneal absorption grew out of a desire for more accurate knowledge concerning the lymphatic system of the diaphragm and its relation to the lymphatics of the lungs in the leading experimental animal, the dog. Excellent descriptions, adequately illustrated, of the lymphatic distribution in this region in man are available in standard textbooks on anatomy, but adequate descriptions of the system in this region in the dog are not available. Sisson² con-

tributed little if any data on the lymphatics of the diaphragm and their relations to the lung. Since the dog is being used more and more as an experimental animal, it is increasingly important to obtain such data. Furthermore, the exact relationship of the lymphatic system to the vascular system is inadequately understood. The fact that normal lymph so often contains large numbers of erythrocytes leads one to question the generally accepted statements that the lymphatic system is a closed one. Accordingly, it may be worth while to seek further detail bearing on this most important but little understood lymphatic organization.

Many excellent reports of experimental studies on the absorption of particulate matter from the peritoneal cavity, with special reference to the reactions of free phagocytic cells, are available. The mode of transfer of such particulate matter into the diaphragmatic lymphatics, whether through definite stomata as originally advanced by von Recklinghausen,³ or directly through the cell bodies, are among the questions discussed. MacCallum⁴ denied the existence of stomata and attributed absorption to the activity of free phagocytic cells. The pumping action of the respiratory movements facilitated the passage of these phagocytic cells into the lymph stream, although in the absence of such macrophages the mechanical factors involved literally forced free particles through the wall of the lymph channel.

Various injecting mediums have been used in the earlier studies of peritoneal absorption. Buxton and Torrey⁵ recovered nucleated blood cells from the mediastinal lymph nodes fifteen minutes after their intra-peritoneal injection into a guinea-pig. Bolton⁶ employed lampblack, bacteria and nucleated blood cells in his study of absorption, and concluded that the drainage is a purely mechanical process, the force being supplied by respiratory movements, and that the particles pass between the epithelial cells of the diaphragm. Bolton briefly commented on the position of the lymph channels which drain the diaphragm. Cunningham⁷ injected into the peritoneal cavity of cats a solution consisting of washed nucleated blood cells, unfiltered carbon particles and lamp-

black granules in isotonic sodium chloride solution. In three minutes all three types of material had reached the anterior mediastinal lymph nodes, but were all free in the sinuses. The foreign particles had not been phagocytosed in their transfer to the lymph stream, but moved freely into the surface cells of the diaphragm. In Cunningham's study on the absorption from the peritoneal cavity in the fetus, respiratory movements seem intimately correlated with the extent of absorption. Such movements of the diaphragm literally force the particles into the cells where they are carried through the endothelium into the lymph duct.

Cunningham,¹ in a complete review of the physiology of serous membranes, concluded that at least a large proportion of the particulate matter passes through, and not between, the cells in the course of its absorption into the diaphragmatic lymphatics from the peritoneal cavity. He further concluded that one significant factor in the absorption of particulate matter through the mesothelial cells is by means of the pressure of the diaphragm on the intra-abdominal viscera. Florey,⁸ in studies on the rabbit, concluded that foreign particles pass from the peritoneal cavity between the mesothelial cells of the diaphragm into the lymphatic trunks and not directly through the cytoplasm of these cells. Florey supported the original thesis of MacCallum (1903), but did not substantiate the observations of Cunningham (1922). Poynter⁹ has conducted extensive experiments on the absorption of true solutions, colloids, bacteria and particulate matter from the peritoneal cavity, and concluded that lymphatic channels, except those related to the diaphragm, play but an insignificant part in the absorptive process. The venules of the omentum are shown by Poynter to be the more important avenue, because various colloidal particles have been recovered from the portal blood and the liver. The mesenteric lymphatics, the receptaculum chyli and the thoracic duct were never found to participate in the drainage from the peritoneal cavity. More recently Brown,¹⁰ in an experimental investigation to determine the value of lymphaticostomy, concluded that in rabbits the main path of absorption from the peritoneal cavity is by the thoracic duct, but in dogs and cats this route plays only a subsidiary part. He concluded that lymphaticostomy cannot be recommended in cases of acute peritonitis. Although we have observed the mode of absorption and the nature of the particulate matter in the lymph stream in a number of instances,

we shall not report them here, since this paper is restricted entirely to a consideration of the lymphatic channels which are involved in the drainage of particulate matter from the peritoneal cavity in the dog.

METHODS OF STUDY

Various types of particulate matter have been used from time to time in the study of peritoneal absorption. Florey used hemoglobin, india ink, and suspensions of carmine and cream, but his best results were obtained by using finely particulate graphite, first described by Drinker and Churchill,¹¹ and known as "Hydrokollag 300." Higgins and Murphy¹² modified somewhat the method of making the suspension described by Drinker, and greatly reduced the interval required to perfect the final product. When made correctly and thoroughly centrifuged the final preparation is a homogenous mass of particles many times smaller than erythrocytes. The preparation may be injected directly into the blood stream of mammals without causing any reaction, and thus it provides an admirable means for the study of the reticulo-endothelial system. We have used the graphite preparation repeatedly for studies on the von Kupffer cells of the liver, the reticular cells of the spleen and the phagocytic cells of serous cavities, and have found it an entirely satisfactory injection mass.

OBSERVATIONS

If a given quantity of the final graphite preparation, the amount varying with the size of the animal, is introduced into the peritoneal cavity of a dog, the lymphatics of the diaphragm are soon visible with the injection particles. In periods ranging from ten minutes to an hour and a half the lymphatic channels on the pleural surface of the diaphragm are completely delineated (fig. 1). Muscular activity appeared to hasten the absorptive process for, in animals exercised during the interval following the intraperitoneal injection, the lymphatics were more readily and more completely filled. Massage of the wall of the abdomen and chest further facilitated absorption, and since the process seemed greatly retarded in animals suffering with distemper or other pulmonary disability, respiration played a significant part in the removal of such particulate matter from the peritoneal cavity.

One hour after the peritoneal injection of from 40 to 50 cc. of the graphite preparation, the lymphatic channels on the pleural surface of the diaphragm were well distended and their distribution could be

readily traced. Although some variation in the extent and distribution of the lymphatic pattern maintained in different animals, yet in the twenty-five dogs which comprised our series, the more characteristic picture is that shown in figure 1. It must be recalled that the lymphatics here illustrated are those functionally active in such normal absorptive processes, delineated only by the graphite and not by the injection method hitherto commonly employed.

Fig 1.—The pleural surface of the diaphragm in a dog after the intraperitoneal injection of the graphite preparations. The lymphatic channels of the diaphragm are distended.

Figure 1 shows that the distribution of the lymphatic channels is much greater on the right hemidiaphragm than on the left. The reason for this is not clear, although the proximity of the large right hepatic lobe, providing greater contact surface during respiration, may be a factor. Prolonged massage of the left side of the chest and abdominal wall, however, failed to reveal more lymphatic channels on the left hemidiaphragm than could be seen during the normal process of absorption. The main collecting trunks of the diaphragm lie below the pleura,

on the muscle bundles, and pursue in general a diagonal course from the crura to the para sternalis. These larger channels, restricted for the most part to the medial portion of the muscular area, form a rather prominent plexus as they continue toward the sternum, and the smaller lymphatic vessels which arise along the costal attachment pursue more or less parallel courses and empty into the major plexus. The central tendon is relatively devoid of lymphatic channels. Smaller capillaries, however, are frequently discerned along the margins of the tendons, whence they empty into the larger vessels of the muscular portions and occasionally small channels drain across the central tendon from one muscular portion to another, particularly if the flow is toward the thoracic duct.

There are five drainage routes by means of which the absorbed material is removed from the diaphragm. The first of these is the sternal route, by far the more effective, which receives the drainage from the pars sternalis, pars costalis and to a certain extent from the pars lumbalis. From the standpoint of size and distribution the four remaining routes are apparently of equal significance in lymphatic drainage. The first of these, and perhaps physiologically and pathologically the most significant, comprise a variable group of small lymphatic capillaries which arise, partly in the pars sternalis, just ventral to the central tendon and partly from the muscular portion dorsal to the tendon. This group of small lymphatics, generally more conspicuous on the left side, leaves the diaphragm, courses forward along the pericardium, often parallel to the esophagus and the vagus, to the bronchial lymph nodes which lie dorsal to the base of the lung (fig. 2). Further drainage from this portion of the diaphragm is effected by a small lymphatic channel which usually arises in a small node and courses forward along the phrenic artery and nerve to a lymph node in the anterior mediastinum (fig. 2). The third route, effecting the anterior drainage of the lymph from the diaphragm is by way of the thoracic duct. The dorsal portion of the pars costalis and a portion of the pars lumbalis are drained by a varying number of small lymph channels which empty directly into the thoracic duct. The relative quantity of lymph which pours into the thoracic duct from the diaphragm is exceedingly small; in numerous experiments following the intrathoracic cannulation of the thoracic duct in animals which had received the peritoneal injections of graphite, free particles were rarely encountered in the thoracic lymph. In a single case, rapid appearance of the graphite in the thoracic duct suggested an unusual distribution of the diaphragmatic channels, and subsequent necropsy revealed an exceedingly large channel emptying directly into the thoracic duct. The thoracic duct is a variable structure in the different dogs. It is often double, somewhat

plexiform and passes forward usually to the right of the aorta and ventral to the azygos vein.

The other two lymphatic routes, draining a portion of the diaphragm, lead into the peritoneal cavity or into the retroperitoneal spaces dorsal to the two diaphragmatic crura. Of these two, the latter course is the more extensive and the more constant in its distribution. In figure 1 lymphatic channels are shown in the lower right and lower left margins of the diaphragm, which carry a portion of the lymph backward, dorsal to the peritoneum, to a large lymph node which lies in the retroperitoneal space just above the kidney; thence different channels pass obliquely to the cisterna. In figure 2 a group of three or four lymphatic channels are shown along the dorsal portion of the wall of the chest, coursing relatively parallel to the aorta. These channels, which readily distend with graphite when it is introduced into the peritoneal cavity, join those coming from the adjacent portion of the diaphragm and together course posteriorly to the retroperitoneal node described. Figure 1 shows also a group of three lymphatic channels which course over the dorsal half of the diaphragm and converge near the ventral margin of the aorta. These channels then course directly through the diaphragm, enter the peritoneal cavity, and may be traced directly to a lymph node in the mesentery of the spleen. Invariably these mesenteric nodes are black when the injection residue is washed from the peritoneum, but the extent of the vessels coursing from the diaphragm into the peritoneal cavity is a variable one. In certain dogs we were able to recognize them with great difficulty, and in others such peritoneal channels coursing directly from the diaphragm could be traced directly to the lymph nodes near the spleen, the kidney, and in some instances to the pancreas of Aselli.

We shall summarize briefly the lymphatic drainage from the diaphragm of dogs previously given injections of the graphite preparation. There are five routes through which such particulate matter is removed: the sternal, the pulmonary, the thoracic duct, the retroperitoneal and the direct peritoneal routes. Of these, the sternal route is essentially the most conspicuous and probably carries away four-fifths or more of the material removed from the peritoneal cavity. The pulmonary route is perhaps the next efficient, followed by the thoracic duct, the retroperitoneal lymph ducts, and, lastly, the direct peritoneal course, if one is to judge by relative distensibility following peritoneal absorption.

In the dog, then, the major drainage from the diaphragm is through the sternal lymphatics. In the slightly reflected portion of the sternum, as shown in the upper portion of figure 1, a group of three or four channels course from the diaphragm into the spaces between the intercostal muscles and continue forward, parallel to the sternal or thoracic

artery and vein. Occasionally, plexuses are formed by these channels around the blood vessels. These sternal lymphatic trunks continue into a series of two to four lymph nodes which lie in the interval between

Fig. 2.—The right half of the thorax removed from a dog after intraperitoneal injection of the graphite. The lymph channels and nodes are shown, together with their relation to the thoracic duct.

the first and third ribs (fig. 2). Throughout their forward course the lymphatics on the two sides of the sternum are independent of each other, but in the region of these sternal lymph nodes numerous collecting

branches unite the two (fig. 3). Thence, the lymphatic drainage may be in any one of three directions: directly through collecting channels which course through the fascia along the right innominate vein to the right lymphatic duct and enter the venous system at the right jugular subclavian confluence; through anastomosing channels and additional nodes directly to the thoracic duct near its venous confluence, or by way

Fig. 3.—Dorsal view of the mediastinal region in a dog, showing lymph nodes and associated lymph channels in a dog given an intraperitoneal injection of the graphite preparation.

of a paratracheal mediastinal lymph node (fig. 3). The pattern of the lymphatic distribution in this region is a variable one, and an attempt will not be made to give in detail the various courses which our dissections have revealed. In general, the drainage from the right sternal lymphatics is to the right lymphatic duct; drainage from the left sternal lymphatics, with the exception of certain anastomoses, is toward the thoracic duct.

Figure 2 shows the drainage from the left side of the diaphragm through the pulmonary region. On the right side, the lymphatic channels from the diaphragm to the hilum of the lung are far less conspicuous, and yet in nearly every animal studied one or more such vessels were seen leading directly to parabronchial nodes on the right side. The lymph duct which courses forward over the pericardium, parallel to the phrenic nerve is invariably present. This empties directly into a paratracheal mediastinal lymph node, lying directly on the ventral surface of the trachea, somewhat anterior to the arch of the aorta. Other channels leave the diaphragm in the region of the central tendon, incline somewhat dorsally and course either through the pulmonary mesentery or along the esophagus parallel to the vagus nerve. This group of lymphatics enters the parabronchial nodes, usually two or three in number, which lie within the arch of the aorta just dorsal to the base of the left lung (fig. 2). We have never observed any direct lymphatic continuity between these diaphragmatic channels and the tissue of the lung. The pulmonary lymph channels, however, communicate directly with these parabronchial nodes and accordingly any retrograde flow of lymph would permit dispersion of the particulate matter of the peritoneal cavity within the lung. The discoloration of the lung in a number of dogs would suggest such a reversal, and yet the varying degrees of anthracosis which occur in the average dog render such a conclusion untenable.

Anterior to the parabronchial nodes, the lymph drainage continues by way of channels which pursue rather different courses in different animals. The more usual pattern encountered is that illustrated in figure 3. A group of from five to eight channels continues forward from these bronchial lymph nodes to a series of mediastinal nodes which lie in the fascia along each side of the trachea, the brachiocephalic artery and the anterior vena cava. A considerable portion of the lymph from the nodes on the left bronchus passes through channels which lie dorsal to the aortic arch, to the more posterior mediastinal node, which lies adjacent to the brachiocephalic artery, and receives the drainage from the right bronchial nodes as well. Other channels from the left bronchial nodes course directly forward ventral to the aortic arch and empty into the paratracheal node at a considerable distance anteriorly. Figure 3 shows that the drainage from the right side of the pulmonary region, and no doubt to a considerable extent from the left, empties into the venous circulation through the right lymphatic duct. The principal drainage from the left side, however, although exhibiting certain anastomotic arrangements with that of the right, is more largely forward through a series of two or three nodes which lie along the left side of the trachea and which ultimately connect by additional channels with the thoracic duct near its venous confluence.

The third anterior drainage route from the diaphragm is by way of the thoracic duct. As shown in figures 1 and 2, only a few small lymphatic channels ordinarily pass from the diaphragm into the thoracic duct. Accordingly, this route is of relatively small significance in the drainage of particulate matter from the peritoneal cavity. The duct, somewhat plexiform in arrangement, courses forward to the right of the aorta and ventral to the azygos vein, much as is shown in standard comparative textbooks, forms the characteristic ring around the base of the jugular vein and empties into the vascular circulation either at the subclavian confluence or into the left innominate or left brachiocephalic vein.

SUMMARY AND CONCLUSIONS

From this rather cursory survey of the anatomic relations of the lymphatic channels which function in the removal of particulate matter from the peritoneal cavity of the dog, it is evident that the thoracic duct plays a relatively insignificant part. Particulate graphite, when injected directly into the peritoneal cavity, is readily visible in the diaphragmatic lymphatics and the sternal trunks within from ten to twelve minutes in normal healthy dogs. In animals, however, in which the respiratory mechanism is disturbed, so that the normal excursion of the diaphragm is modified somewhat, the interval between the peritoneal injection and the appearance of the graphite in the sternal lymphatics is greatly prolonged. The injected graphite is visible in the sternal lymphatic trunks usually long before it can be identified in the cannulated thoracic duct. In only one dog of our series, a more or less rapid appearance of the pigment in the thoracic duct was explained at necropsy when an unusual distribution of the lymphatics of the dorsal portion of the diaphragm was discovered to include major channels which were directly confluent with the thoracic duct. Ordinarily, the lymph of the thoracic duct is colored only lightly and then only after prolonged intervals, when the lymphocytes within it contain large numbers of the graphite particles, probably phagocytes within the peritoneal cavity. With the animal under ether anesthesia, it is relatively simple to open the median line of the chest in the region of the first or second costal cartilages and thus expose the sternal or thoracic blood vessels. In this way the region may be watched and the first appearance of the black graphite in the clear lymph of the channel may be noted. Preparations made of the lymph coming through these channels show that the graphite contained within it is in the free particulate state, just as it was injected into the peritoneum. On the other hand, smears made from the lymph nodes in this region, as well as fixed paraffin sections, show that the material is both in the cells and in the free state, the particles having been phagocytosed by the large cells of the lymph node.

If in the same animal, or in one subjected to the same injection into the peritoneum, a cannula is introduced into the thoracic duct in the neck near its venous confluence, samples of lymph may be taken for analysis. Within thirty minutes, following the peritoneal injection, darkly colored lymph may be recovered from the thoracic duct in the neck. Analysis shows that the graphite contained therein is partly free and partly in the large lymphocytes. The cells containing the graphite are probably derived from the lymph nodes of the pulmonary, the tracheal or the sternal regions; the particles in the free state have passed directly into the lymph stream from the diaphragm.

By means of insufflation, one of us (Graham) was able to develop a technic whereby the thoracic portion of the thoracic duct could be cannulated and samples of lymph could easily be collected for analysis of cellular content. In a number of experiments, lymph was collected from the thoracic duct of dogs that had previously received a peritoneal injection of the graphite preparation. The sample taken immediately after the intraperitoneal injection was normal lymph with the usual number of small and large lymphocytes. During the first hour, long after the sternal lymphatics were black, there was no evidence of the graphite either in the free state or in phagocytic cells, yet there was an apparent increase in the number of large lymphocytes. An hour and a half following the injection, the larger cells of the lymph contained many granules of graphite, but the smaller cells were entirely devoid of them. There were no free particles in the lymph stream at this time. Subsequently, with an increase in the number of these large cells, small quantities of free graphite appeared in the lymph. Also, at intervals of about two hours following the injection, the larger cells contained the graphite in varying quantities, and in many cases the cytoplasmic bodies were literally packed with granules. Analysis of the peritoneal exudate showed masses of cells, similar to those recovered from the thoracic duct, packed with the graphite material. Unquestionably, these cells of the thoracic duct are identical with those in the peritoneal exudate, and they had probably entered the cisterna after phagocytosing the graphite in the peritoneal cavity. The particles of graphite which were encountered free in the lymph of the thoracic duct probably entered the duct through the few small channels coming from the dorsal margins of the diaphragm. Samples of blood taken from the femoral artery at this time contained occasional granules of free graphite, together with cells moderately packed with the injected material.

If one is to judge by the degree of physiologic activity and the number of lymph channels leading from the diaphragm it is apparent that the lymphatic paths coursing through the pulmonary region are more effective in removing foreign particles from the diaphragm than the thoracic duct. These channels are not large and by no means com-

parable to those which run along the sternum, and yet they are invariably present on the left side, coursing forward through the related mesenteries to the lymph nodes at the base of the lung, and usually are identified on the right side, although perhaps to a less degree.

In the removal of foreign particulate matter or bacteria from the peritoneal cavity, these pulmonary lymphatic routes are perhaps the most significant from the standpoint of pathology. Although these channels are not directly confluent with pulmonary lymph vessels yet they join with them in the nodes which lie at the base of the lung. In these nodes the lymph draining the two regions mingles and courses forward in the channels of the mediastinum. Accordingly, although direct pulmonary contacts with peritoneal drainage is not effected, nevertheless any disturbance in the flow or lymph coming from the lung, so as to involve stasis or even a retrograde flow, could well infect the lung with peritoneal organisms. These observations do not warrant such conclusions, for the pigmented lung so often encountered in these experimental animals has, of course, other explanations. The common pulmonary complications which accompany abdominal operations on dogs, however, may have their explanation in the lymphatic association of the two regions.

OLD NODULAR GOITER SURROUNDING TRACHEA, POSTERIOR TO THE CAROTID WITH THE ISTH- MUS POSTERIOR TO THE ESOPHAGUS

REPORT OF A CASE WITH SUDDEN DEATH FROM ACUTE ABSCESS*

MILES F. PORTER, M.D.

FORT WAYNE, IND.

History.—S., a man, aged 60, was brought to the hospital suffering from retention of urine due to an enlarged prostate. He had a large, nodular, hard goiter which was fixed and which he said never bothered him. However, on inquiry, it was found that for six or eight months he had been unable to breathe well when lying flat, and that for the same length of time his voice had been affected. There were no toxic symptoms. He had had the goiter "ever since he could remember."

Catheterization, with the usual treatment after ten days or two weeks, put the patient in a condition for operation. A two-stage prostatectomy was done on December 24 and January 15, respectively. The patient was making an ideal recovery until January 21, when he had a chill accompanied by severe pain in the right side of the goiter and a temperature of 103.4 F. He also complained of difficulty in breathing. On the next morning when I saw him, he was sitting in bed reading the paper, and complained only of some soreness in the right side of the goiter. The temperature dropped to normal that night, and on the 23d he was feeling quite well, with a slight elevation of temperature and some soreness still present in the goiter. Early the next morning (the 24th), he complained of severe pain in the neck and difficult breathing. Within ten minutes he was dead.

The nurse in charge of the floor also reported that the goiter was greatly increased in size, and that the man was cyanotic and evidently died from asphyxia. Both drains were removed from the bladder on the 23d when the cystotomy wound seemed to be in a good condition, and the drainage was satisfactory.

Autopsy.—Autopsy was performed three hours and thirty minutes after death. The bladder, the area around the prostate and the cystotomy wound were clean and normal. The abdomen was normal, except for stones in the gallbladder. Extensive pleural adhesions (old) were found on the left, and there were some on the right, also. The left ventricle was slightly hypertrophic. The cardiac vessels and valves were normal. No thrombus or embolus could be found.

The large goiter was uncovered with difficulty on account of close old adhesions; during the process of uncovering it, an abscess on the right side was opened and discharged more than an ounce of sanious pus, which was found to be streptococcic. Sharp dissection was necessary in removing the gland, which was closely adherent throughout its entire surface.

The right lobe (the larger) was crossed vertically on the outer anterior aspect by a white, flat band, which proved to be the carotid artery (fig. 1). This was separated from the gland, and the latter was removed in its entirety. The right lobe crossed over the trachea and was intimately adherent to the front of the

* Submitted for publication, April 2, 1929.

left lobe, and the isthmus was behind the esophagus. Thus, the esophagus and trachea were completely encircled by the goiter (fig. 2).

Figure 1 is a drawing that I made from memory immediately after the removal of the gland. Neither the artery, the trachea nor the esophagus was removed with the goiter but, to make the interpretation clearer, the drawing was made as though they had been. The artery should appear more flattened than it does in the drawing.

Figure 2 is a schematic representation of a cross-section showing the relation of the artery, the trachea and the esophagus to the goiter, also the location of the isthmus. Microscopic examination of several sections showed no malignant disease but old and recent inflammatory reactions.

Fig. 1.—Drawn immediately after removal, from memory. *C.C.A.*, flattened carotid; *D.*, dent in trachea made by pressure of goiter; *T.C.*, thyroid cartilage; *T*, trachea; *E*, esophagus; *I*, isthmus; *R.L.* and *L.L.*, right and left lobes, respectively.

COMMENT

In my opinion, the sudden death in this case was due in the main to an acute streptococcic abscess. The source of the infection was not determined.

The universal close adhesions prove the existence of a long-standing, low-grade inflammation, an exacerbation of which may have been caused by the lowered resistance consequent on the urinary trouble, plus the operation. It should be added that examination of the specimen after removal showed several additional abscesses.

The asphyxia may have been in part, at least, due to pressure on the superior laryngeal nerve, as the abscess was located in the upper right aspect of the gland. However, the dent remaining in the trachea after the gland was removed shows that the capacity of that tube had been encroached on for a long time.

From the flattening of the carotid, one would suppose that the passage of blood through this vessel was considerably inhibited. If so, there were no clinical signs indicative of it.

I never saw the isthmus located behind the esophagus before, nor have I found a similar case reported, although, as is well known, unusual forms of this part of the thyroid are not infrequent. Absence of the isthmus or of one of the lobes is not extremely uncommon; it is quite possible that in the case reported, the isthmus and the left lobe were never developed and that what seemed to be the isthmus was really an extension of the right lobe of the gland, as was what I have named the left lobe.

Fig. 2.—Schematic drawing of cross-section, showing relation of artery (C.A.), esophagus (E) and trachea (T) to the goiter. L.L., left lobe; R.L., right lobe; I, isthmus.

Pemberton¹ reported a case (fig. 3) in which there was a mass of thyroid tissue behind the trachea and esophagus which had developed from the right lobe and had formed a tumor on the left side from which the lobe had previously been removed. Hertzler sent me a photograph of a case much like Pemberton's (fig. 4), except that the growth was malignant.

Graham² referred to a case reported from Hoffman's Clinic by M. Willenbacher, in which the goiter completely encircled the trachea, producing dyspnea in a new-born child, and which was successfully removed forty-three hours after birth.

The distortion of the great vessels that was present in the case here reported has been seen in "several instances" in the Lahey Clinic³ in

1. Pemberton: Surg. Clin. N. Amer. 6:1278 (Oct.) 1926.

2. Graham: Practical Medicine Series, Surgery, Chicago Year Book, 1928, p. 211.

3. Clute, H. M., and Smith, L. W.: Cancer of the Thyroid Gland, Arch. Surg. 18:part 1, 14 (Jan.) 1929.

Fig. 3.—Cross-section of a huge retrotracheal projection, forming a tumor on the left side of the trachea from which the lobe had been previously removed. (From Pemberton: *Surg. Clin. N. Amer.* 6:1278 [Oct.] 1926.)

Fig. 4.—Postmortem specimen from Herten's case of sarcoma.

patients with cancer of the thyroid. Lahey⁴ said that they have never had a case like the one here reported. Albert Kocher⁵ referred to an outward displacement of the vessels so that the "carotid is felt in the external posterior portion of the tumor underneath the skin and along the outer border of the sternocleidomastoid muscle," but made no mention of such distortion as occurred in this case.

Crotti⁶ spoke of the displacement of the vessels much as Kocher did, but made no mention of anterior displacement.

Neither Ochsner⁷ nor Crile,⁸ in their works on goiter, mentioned derangement of the vascular relations such as is herewith reported.

C. H. Mayo⁹ said that he had seen "a few cases, not more than four" like the one reported here.

Crotti,¹⁰ said that he had seen eight or ten cases of "circular goiter in which the two lobes came in contact behind the esophagus."

SUMMARY

A case is reported of sudden death from asphyxia due to an acute streptococcic abscess engrafted on a chronic inflammation in an old, nodular, nonmalignant goiter, which completely surrounded the trachea and esophagus with the isthmus behind and the lateral lobes meeting in front of the trachea, and having the carotid vessels stretched over the front of the right lobe. It is probable that both the anterior dislocation of the vessels and the retrotracheal projection of the gland are more likely to occur in malignant goiters.

Cases similar in some respects are referred to, but after considerable inquiry by letter and research in the literature, no case like the one here reported has been found.

THE EFFECT OF INTRABRONCHIAL INJECTIONS OF IODIZED POPPY SEED OIL 40 PER CENT

AN EXPERIMENTAL STUDY ON DOGS *

RALPH BOERNE BETTMAN, M.D.
Associate Attending Surgeon, Michael Reese Hospital

JOHN KELLY, M.D.
Resident Pathologist, Michael Reese Hospital

AND

NATHAN CROHN, M.D.
Assistant Attending Surgeon, Michael Reese Dispensary
CHICAGO

When iodized poppy seed oil 40 per cent was first advocated in intrabronchial instillation for the purpose of lung mapping, there seemed to us to be several theoretical objections. One of these was that a fibrosis of the lungs would be produced as a result of prolonged presence of an intrabronchial foreign body (iodized oil). Another was that bronchitis or bronchopneumonia would develop due to the transplantation of bacteria from the pharynx into the finer bronchioles by means of the oil. Long before we found experimentally that this second objection was theoretical only, we were convinced by reports of the clinics in which iodized oil 40 per cent had been taken up enthusiastically from the start that bronchitis and pneumonia did not follow its use.

The validity of the first objection, however, seemed to us to be strengthened as we began to see patients a year or two after the injection of iodized oil in whom traces of the oil remained visible roentgenographically. Also, Pinkerton¹ reported several cases of children in whose lungs marked fibrosis had occurred following the aspiration of small quantities of petrolatum which had been instilled into the nose for some local nasal condition. Finally, in our own hospital, Dr. Irving Stein found marked fibrosis of a fallopian tube which contained iodized oil several months after the oil had been instilled into the uterus for the purpose of mapping the uterine cavity and tubes.

EXPERIMENT

Our experiment consisted of intrabronchial injection of a small quantity of iodized poppy seed oil 40 per cent into dogs; the animals

were then killed at various intervals from a few days to seven months after the injection, and the lungs were studied roentgenographically, macroscopically and microscopically.

The technic carried out was identical in all dogs.

The animals were given hypodermic injections of morphine of sufficient strength to make them drowsy and docile, but not enough to put them to sleep.

They were placed on a fluoroscopic table and strapped to a board. Their mouths were held open by an assistant, and a tube (soft rubber French catheter no. 12)

Fig. 1.—Roentgenogram taken immediately after the injection of iodized oil into the lower branch of the right bronchus.

was quickly slipped through the posterior pharynx into the trachea and fed downward until its tip was in one or the other of the two main bronchi. Then from 5 to 20 cc. of iodized oil was injected into the bronchus under fluoroscopic control. The amount varied according to the size of the dog. Sufficient iodized oil was injected to outline clearly the bronchus and bronchioles of one or two lobes of a lung. The catheter was withdrawn and a roentgenogram immediately made.

The dogs were allowed the liberty of the kennels. At frequent intervals, roentgenograms were made.

The dogs were killed at lengths of time varying from a few days to seven months after the injection of iodized oil. A careful and complete autopsy was

done on each dog. The lungs were removed in toto, and roentgenograms were made before they were examined and sectioned.

Sections were made from every lobe of each lung and were stained with hematoxylin and eosin and sudan III (fat stain).

The control consisted of dogs killed for other experimental work. The lungs were removed in toto; roentgenograms were made, and the lungs were sectioned as in the experimental dogs.

RESULTS

Only two of the twelve dogs developed pneumonia—one dog a few days after injection and one several months after. We feel that these

Fig. 2.—Picture of same dog in figure 1 taken four months later, showing retention of the iodized oil into the lower part of the right lung, and also the retention of the same material in the upper lobes.

two deaths have no bearing on the experiment, as in all our dogs the mortality from pneumonia during the winter of 1926-1927 was greater than this; furthermore, one of these dogs died in an epidemic which killed nearly all the dogs in the kennels at that time.

The fact that ten of twelve dogs did not develop pneumonia would have led us to discard the theoretical objection that iodized oil might cause pneumonia, if the clinical evidence had not already caused us

to do so. Macroscopically, only one dog showed signs of marked pulmonary fibrosis and scarring. This was in a dog in which the iodized oil had been injected one month previously. The appearance of the lung suggested a much older process, and the fact that we have seen dogs into which injections had never been made and which had similar lesions leads us to the conclusion that the fibrotic changes in this case cannot be traced to the iodized oil.

Fig 3—Roentgenogram of lung removed after the dog was killed six months after injection, showing retention of iodized oil

In almost every instance, the oil did not remain in the lobes injected but was quickly dispersed. In every instance almost all of the oil had disappeared by the time the second roentgenogram was taken.

In every case, small traces of iodized oil were seen roentgenographically in the lungs removed at autopsy. That includes the dog killed after almost seven months.

The results of the microscopic examinations were as follows:

The lungs of the dogs into the bronchial tree of which iodized oil had previously been injected did not differ grossly in any way from the

lungs of control animals. Microscopically, slight changes were present in the dogs given iodized oil. These changes were not constant in all the sections and did not vary in degree in any single section. Sections taken from those areas which showed a slight degree of mottling in the roentgenogram taken of the bare lungs after autopsy did not present signs or changes any more unusual than those in areas which were clear in the roentgenograms.

Fig. 4.—The portion of the lung which on roentgen examination was shown not to contain iodized oil. It is impossible to distinguish this section from sections of the control animals.

In sections stained with hematoxylin and eosin in both the dogs given iodized oil and in the control animals, a moderate number of large mononuclear phagocytes containing small particles of pigment occurred beneath the pleura. The number and distribution of these cells were about the same in the two sets of dogs. These cells often occurred in the region of small anthracotic areas, or occurred singly.

In the animals given iodized oil the terminal bronchioles were slightly more prominent than those of the controls, and there occurred a slight

increase in the thickness of the wall and a not prominent infolding of the epithelium. The number of lymphocytes in the walls of the bronchi was about the same in the two sets of animals.

In the dogs given iodized oil, small focal areas of fibrosis occurred occasionally beneath the pleura and about the terminal bronchi, and while similar areas occurred in the control animals, their frequency and size were slightly more prominent in the dogs given iodized oil.

Fig. 5.—The lower lobe of the right lung, showing a slight thickening of the parenchyma. In the control dogs, apparently normal lungs showed areas indistinguishable from these.

In sections stained with sudan III, the number of macrophages containing small refractile globules of fat were slightly increased in the dogs given iodized oil. These macrophages occurred beneath the pleura, usually about a small area of anthracosis, but frequently appeared singly. An occasional lining alveolar cell containing small fat globules was present.

The larger bronchi of the dogs given iodized oil infrequently showed fat within the wall. This small amount of fat was located within the fat cells.

The conditions just described were not prominent in any of the sections taken from the lungs of dogs given iodized oil. They were present to a slightly less degree in the lungs of control animals.

Our results have led us to drop our theoretical objections to the use of iodized oil. Our results correspond with clinical experience and also with experimental observations published by others.

We were keenly interested in the result of Pinkerton's² experimental work. He showed results almost identical with our own when iodized oil was used, and results similar to those found in the lungs of children when mineral oils were used. He advanced the explanation that the difference in the reaction might be explained on the basis of the presence of specific ferments-lipases. At the suggestion of Dr. Schultz, the director of the Nelson Morris Institute, we attempted to show the presence of these ferments in lung tissue. However, the usual methods did not give results, showing that if these ferments do exist in lung tissue they exist in small quantities, perhaps in quantities not greater than those found in the circulating blood.

SUMMARY

Instillation of iodized poppy seed oil 40 per cent into the bronchial tree of dogs is not followed by pneumonia nor, as far as we could see, by any acute cellular reaction.

Most of the iodized oil is speedily expelled by coughing.

Small amounts of the oil are retained for at least seven months.

The presence of this iodized oil apparently does not cause a definite foreign body reaction.

INTESTINAL OBSTRUCTION

EXPERIMENTAL STUDIES ON TOXICITY, INTRA-INTESTINAL PRESSURE AND CHLORIDE THERAPY *

FORRESTER RAINE, M.D.

AND

MARGARET C. PERRY, M.A.

MILWAUKEE

In spite of the large amount of experimental and clinical work done on intestinal obstruction, there are still numerous insular concepts of the cause of death, and there are differences of opinion as to treatment. There have been several excellent reviews of the literature during the last few years, and Cooper has recently published an admirable analysis of the situation from the experimental evidence at hand. Since this literature is available, we shall not attempt to review past evidence but shall report the results of our experiments and our deductions as to the manner of treatment likely to be most beneficial for patients having intestinal obstruction.

There is general agreement that simple obstruction differs materially from obstruction with strangulation. This study deals only with simple obstruction.

There have been three primary purposes in these experiments: (1) to determine the toxicity of the content of obstructed intestine when it is present in obstructed and nonobstructed bowel; (2) to determine the effects of varying intra-intestinal pressure on the length of life after obstruction is induced, and (3) to determine the therapeutic value of sodium chloride under varying conditions of intra-intestinal pressure.

The attempt to answer these questions has necessitated inquiry into several subsidiary issues which will be discussed as they appear.

Rabbits have been used as the experimental animals. They are not so satisfactory to use as dogs, for they are more delicate and live a shorter period after obstruction. This disadvantage is more than offset in these particular experiments by the fact that rabbits do not vomit and therefore their intra-intestinal pressure can be controlled.

TECHNIC OF PROCEDURES

All operations, except the second stage of some jejunostomies, were done with the animals under ethylene anesthesia with no preliminary medication. The animals were denied food for forty-eight hours but were allowed water preoperatively. Operations were performed under aseptic precautions, and virtually no wound infections developed.

* Submitted for publication, March 30, 1929.

* From the Laboratories of Columbia Hospital.

Obstructions were created in two ways. Temporary obstruction was produced by making an aperture in the mesentery just beneath the bowel and passing a one-fourth inch rubber band through the opening. The ends of the rubber band were brought out through stab wounds in the ventral abdominal wall about three eighths of an inch apart. The ends of the band were then sewed together applying sufficient tension to compress the intestine so as to occlude the lumen but not enough to destroy the blood supply. This tension was applied with the intestine under observation. When the obstruction was to be released, the rubber band was cut and removed without anesthesia. Usually the intestinal contents could immediately be heard passing beyond the point of obstruction. Permanent obstruction was produced by tying umbilical cord tape around the bowel.

Jejunostomies were performed to permit complete drainage of the stomach and duodenum. Although three methods were tried, none was entirely satisfactory. The principal difficulty was in obtaining free drainage with no back pressure as shown by duodenal distention.

The first method consisted of severing the intestine, tying off and inverting the aboral end, placing a small rubber tube in the proximal end and bringing it out through the abdominal wall.

The second method was similar except that no tube was used, and the wall of the intestine was sutured to the skin.

The third method was the most satisfactory and was done in two stages. Under ethylene anesthesia the upper jejunal loop was brought out through the muscles of the abdominal wall and the muscles approximated with the mesentery intervening. The skin was then sutured over the intestine. Several rabbits died of obstruction following this first stage, but some survived and were in good health. The second stage was done under infiltration with procaine hydrochloride. The skin was opened, the intestine severed and the aboral end tied off. Thus there was no soiling of the peritoneum and no change made in the position of the proximal end to interfere with complete drainage.

Gastrostomies were performed in conjunction with several obstructions. After completion of the obstruction, the stomach was sutured to each side of the abdominal incision over a distance of about 2 inches. The stomach was then opened and the mucous membrane sutured to the skin, thus permitting constant emptying of the stomach through the ventral abdominal wall.

Aspiration of stomach content by a catheter through the esophagus was found to be possible only when rabbits had been on an exclusive diet of lettuce, bread and water for from two to three weeks. After forty-eight hours' starvation the stomach was nearly empty, and the secretions accumulating after obstruction could be aspirated through a catheter.

Material to be put into the stomach after the intestine was obstructed was forced through a catheter.

Solutions of dextrose or sodium chloride were injected into the veins of the ear.

Blood for analysis was obtained from the veins of the ear or from the heart.

The nonprotein nitrogen of the blood was determined by the method of Folin and Wu.¹ The blood chlorides were determined by the method of Whitehorn.²

Blood for the determination of the alkali reserve was obtained from the heart and oxalated under oil. The method used was that of Van Slyke and Cullen,³ and Van Slyke.⁴

1. Folin, D., and Wu, H.: *J. Biol. Chem.* **38**:81, 1919.

2. Whitehorn, J. C.: *J. Biol. Chem.* **45**:449, 1921.

3. Van Slyke, D. D., and Cullen, G. E.: *J. Biol. Chem.* **30**:289, 1917.

4. Van Slyke: *J. Biol. Chem.* **30**:34, 1917.

The chlorides in the stomach and duodenal contents were determined in the following manner. A weighed portion of the stomach or intestinal contents was made distinctly alkaline with sodium carbonate, the mixture completely ashed, and the residue dissolved in distilled water containing nitric acid. In all, the equivalent of nitric acid was 5 cc. of a 1.42 specific gravity acid. From this point the procedure was the same as that for the determination of chlorides in the blood.

Some rabbits died from the obstruction sooner than was expected so that complete data on their blood were not obtained. Others contracted pneumonia soon after operation. Records of the experiments on such animals were discarded.

THE TOXICITY OF THE CONTENTS OF OBSTRUCTED INTESTINE

Rabbits vary considerably in the length of time they live after obstructions at similar points in their intestinal tracts. The amount of

change in the nonprotein nitrogen and chlorides in the blood also varies somewhat, but as a rule is a dependable indication of the rabbit's condition. Obstruction in the middle of the duodenum is compatible with life for from fourteen to eighteen hours. Obstruction at the beginning of the jejunum caused death in from twenty-two to thirty hours. The duration of survival increases as the obstruction is lower so that life may last from eighty to two hundred hours when the obstruction is at the terminal ileum. These figures hold for rabbits receiving neither food nor water after the obstruction is created. Death occurs more rapidly if food or water is taken.

Contrary to some opinions, it will be noted that obstruction low in the small intestine causes as great a drop in blood chlorides as that fol-

lowing high obstruction, provided there is a proportionate increase in the duration of the obstruction. There is always an increase in the nonprotein nitrogen of the blood as well as in the alkali reserve.

When rabbits are nearing death from obstruction, there is a great decrease in body temperature. Blood pressure is low, and there is some concentration of blood as noted in the diminished amount of plasma in proportion to the cellular constituents. When the rabbits are sick, it is difficult and sometimes impossible to obtain blood from the veins of the ear, even after application of heat and xylol.

The release of an obstruction when the rabbit is nearing death induces a rapid change in its condition. Within an hour its body tem-

perature has at least approached normal; it bleeds freely and hops around in apparent health. The blood chlorides are well on the way to normal by the end of an hour after release of the obstruction, and within three or four hours they are at or above the normal level. The nonprotein nitrogen of the blood drops soon after release if the rabbit has not been moribund, but when it has been near death the nonprotein nitrogen may increase for a time after the release before there is a return toward normal. The return of the nonprotein nitrogen to normal after release of low obstructions is not so rapid as that after the release of high obstructions.

The removal of the stomach contents before the release of the obstruction retards recovery. Substitution of an equivalent amount of distilled water, although presumably compensating for the loss of fluid,

does not hasten recovery. The blood chlorides remain low, and the nonprotein nitrogen remains elevated until food or water containing chlorides is given. Substitution of an equivalent amount of sodium chloride solution to compensate for the water and chloride removed from the stomach before release of the obstruction hastens recovery more than when distilled water is given but does not permit of rapid return

of blood chlorides and nonprotein nitrogen to normal. Substitution of a solution of hydrochloric acid equivalent to the water and chlorides removed before release induces recovery almost as rapidly as that occurring after release of obstruction without removal of the stomach contents.

Rabbits having had their stomach contents removed before release of obstruction without replacement of chlorides by sodium chloride or hydrochloric acid do not appear entirely healthy. They bleed with

difficulty and are sluggish in their movements until they have been given food or water and their blood constituents return toward a normal level.

Comment.—The experimental observations reveal certain facts concerning intestinal obstruction, a few of which are new. They also justify explanations that may or may not be substantiated.

Rabbits die from obstruction of much shorter duration than do dogs. One rather obvious reason is that there is no vomiting and therefore no release of pressure in the obstructed bowel. Although rabbits do not vomit, the retained secretions are lost to the animal just as much as if vomiting had occurred. The amount of chloride in the contents of the obstructed bowel is sufficient to account for the fall in blood chlorides.

The higher the obstruction, up to the middle of the duodenum, the more rapid the death. It has been proved for rabbits and apparently holds true for dogs that the stomach and duodenum receive practically all the secretions entering the gastro-intestinal tract. These secretions come from the glands in the mucosa of the stomach and duodenum and also from the liver and pancreas.⁵ Loss of all the secretions entering the stomach and duodenum is incompatible with life. The lower the obstruction, the more reabsorption of these secretions, thus retarding dehydration as well as depleting the elements in blood going to form the secretions. During the first twenty-four hours of ileal obstruction there is almost no evidence of change in a rabbit's condition. The blood chloride, nonprotein nitrogen and alkali reserve differ but little from the normal. The animal appears healthy; it is warm and bleeds from its veins readily. During this first twenty-four hour interval reabsorption almost keeps pace with secretion. Since the entire intestinal tract is not available for absorption and none of the secreting portion is excluded, absorption lags behind secretion. Furthermore, as intrainestinal pressure is slowly increased, peristalsis is more vigorous, and secretion is accelerated. The increased amount of secretion augments intrainestinal pressure, giving rise to distention as the intestinal muscles lose their tone. As distention increases, absorption is proportionately retarded and is eventually almost nil. The changes in the blood during this period are great, and the change in the clinical picture is evident. All determinable deviations from normal are the same as those occurring in high obstruction but occur from twenty-four to forty-eight hours later.

In spite of apparent evidence to the contrary, it may be that toxemia plays a minor rôle in simple obstruction and that the real cause of death is the loss of secretions normally reabsorbed. The fact that extirpation of the duodenum has been found compatible with life need

5. Bunting and Jones: *J. Exper. Med.* **17**:192, 1913; **18**:25, 1913.

not alter this conception, for then there is no loss of secretions, the elements forming the secretions never being removed from the blood.

The release of temporary obstructions in rabbits, even when the animal is near death, permits return to health. The reabsorption of the contents of the obstructed bowel through normal intestine below the obstruction or from the obstructed bowel after the tension is lowered instead of showing evidence of the absorption of a noxious substance initiates a rapid return of the animal to normal. The blood chlorides are increased within one hour after release of the obstruction. This increase must be due to reabsorption, for the removal of the bowel contents above the obstruction prior to release does not permit an increase in the blood chlorides. This observation is further confirmation of the concept that the decrease in blood chlorides in obstruction is due solely to loss of stomach secretions. Furthermore, unless chlorides are given, the high nonprotein nitrogen shows no inclination to decrease. Some animals have lived for almost two days after release of jejunal obstructions with low blood chlorides and high nonprotein nitrogen and eventually recovered after the ingestion of food and water containing chlorides.

The removal of the stomach contents prior to release of temporary obstruction and the substitution of solutions of sodium chloride or hydrochloric acid in amounts comparable to the amount of water and chloride removed permit of recovery more rapidly than when distilled water is substituted but not so rapidly as when the obstruction is released without removal of the stomach contents. There are other elements in the secretions besides chlorides, the reabsorption of which benefits the animal.

THE EFFECTS OF DIMINISHED AND INCREASED INTRA- INTESTINAL PRESSURE

Attempts to reduce the intra-intestinal pressure in obstructed bowel were not uniformly successful and entailed additional operative trauma, which must be considered in interpreting results.

Jejunostomy, theoretically, causes only the entire loss of the secretions from the liver, pancreas and the gastro-intestinal mucosa above the segment opened. In the jejunostomies performed an element of partial obstruction was added in spite of efforts to prevent it, for none of the rabbits drained freely enough to obviate some duodenal distention. This presumably shortened the lives of the animals but does not entirely vitiate the observation that the length of life following jejunostomy is but little longer than that following obstruction at the same point. The changes in the blood are identical, and the appearance of the animal is the same.

Removal of the stomach contents every eight hours from an animal whose jejunum is obstructed relieves most of the excess intra-intestinal

pressure, although the duodenum is always moderately distended. This incomplete release of pressure in jejunal obstructions increases the time of survival from eight to fifteen hours.

Reducing intraduodenal pressure in jejunal obstruction by gastrostomy, done at the time the obstruction was created, adds a great deal of operative trauma but, even so, lengthens life from ten to fifteen hours.

The capacity of the stomach, or more likely the duodenum, to absorb water is much greater than has been supposed. Attempts to increase extra-intestinal pressure after obstruction of the jejunum by the introduction of water into the stomach in fairly large amounts were not

successful. The excess water was readily absorbed, for when the animal was killed, there were but little more stomach and duodenal contents than are found in rabbits of the same size after simple obstruction. This work was done during hot weather which probably influenced the results.

The introduction of liquid albolene into the stomach after obstruction of the jejunum gave different results. Since there was no absorption of albolene, intra-intestinal pressure was increased immediately, and death occurred from eight to ten hours sooner than it does after simple obstruction. There was also an increased amount of stomach and duodenal contents, rabbits so treated having about the same amount (albolene discarded) at their death in twenty hours as those with simple obstruction had in from twenty-six to thirty hours. The amount of chlorides in the stomach contents was virtually the same in the two groups.

Increasing intra-intestinal pressure after jejunal obstruction by the introduction into the stomach of stomach and duodenal contents, obtained after twenty-six hours of jejunal obstruction in another animal, shortened the usual length of life and caused a greater increase in the nonprotein nitrogen of the blood than that observed after using albolene.

Since the duration of life is longer after ileal obstruction, increments in intra-intestinal pressure make differences in the time of survival more

apparent. The capacity of the small intestine for the absorption of water is great. Rather large amounts of water introduced into the stomach at short intervals following obstruction at the terminal ileum caused no appreciable increase in intra-intestinal pressure and did the animals no harm. The work was done during hot weather which probably affected the results.

Increasing intra-intestinal pressure by the introduction of liquid albolene into the stomach after obstruction at the terminal ileum shortens life materially. The animals die with as great changes in their blood chlorides and nonprotein nitrogen after the same duration of obstruction as those having high jejunal obstructions.

The effects of the introduction of stomach and duodenal contents, obtained from an animal having jejunal obstruction for twenty-six hours, into the stomach of a rabbit immediately following obstruction at the terminal ileum are not great. The animals are but little more distended at the end of twenty-four hours than are those having simple ileal obstruction, and the deviations of their blood chlorides and non-protein nitrogen from the normal are not much greater.

Comment.—Reducing the pressure that develops within the bowel above the level of the induced obstruction increases the duration of survival and restricts correspondingly the alterations in blood chlorides

TABLE 6.—*The Effects of Increasing Intra-intestinal Pressure in Rabbits Obstructed at the Terminal Ileum. and nonprotein nitrogen. The reasons are definite. As intra-intestinal pressure rises above normal, hyperperistalsis is provoked and continues until the increasing fatigue of the muscularis results in corresponding grades of distention. The rate of secretion is in general directly proportional to the activity of peristalsis. The rate of absorption is inversely proportional to the degree of distention. Thus it follows that increasing intra-intestinal pressure provokes hyperperistalsis which in turn stimulates secretion; the resulting distention diminishes the capacity for reabsorption of these secretions.

The following observation is illustrative. Obstruction of the jejunum was made in the same manner in rabbits of the same size and continued for twenty-six hours. If the stomach contents are removed by aspiration

every eight hours, the total amount obtained is less than when the contents are allowed to collect under increasing pressure for the full period of the obstruction. Longer life after obstruction and restricted alterations in blood chlorides and nonprotein nitrogen provided by reducing intra-intestinal pressure cannot be the result of a decreased absorption of a toxic substance from the lumen of the bowel. The rate of absorption is augmented by reducing tension, and, if an absorbable toxic substance is present, life would be shortened and the symptoms of intoxication would be intensified. Available evidence indicates that survival is longer when intra-intestinal pressure is reduced because there is not so great a loss of the constituents forming the secretions that enter the stomach and duodenum.

The increase of intra-intestinal pressure in jejunal obstruction induced by the introduction of 120 cc. of albolene into the stomach stimulates secretion and retards reabsorption. Blood chlorides are just as low at the end of nineteen hours as they are after twenty-six hours when the pressure is not thus increased. The distention in itself is not the cause of early death, for these animals are greatly distended immediately after obstruction. They seem perfectly healthy until a few hours before death when the typical lethal symptoms develop.

The greater deviation from the normal level of the nonprotein nitrogen of the blood noted after increasing intra-intestinal pressure by introducing 120 cc. of the contents of obstructed bowel from another animal is difficult to explain. Clinically, these animals appeared no worse than those given albolene. It is possible that a larger series would show different results. The only plausible explanations are the presence of a noxious product in the stomach and duodenal contents introduced or that the contents introduced are sufficiently irritating to stimulate secretion more than does albolene.

The untoward effect of increasing intra-intestinal pressure following obstruction at the terminal ileum is evident. When pressure is not increased, there is an interval of about twenty-four hours in the animals with low obstructions before reabsorption lags too far behind secretion. The introduction of liquid albolene immediately after the obstruction is produced seems almost entirely to inhibit reabsorption as well as indirectly to stimulate secretion so that the animals die almost as quickly as do those having duodenal obstructions. The fact that the blood chlorides and nonprotein nitrogen are approximately the same as those found after the same duration of duodenal obstruction makes it evident that death is not due solely to distention. Furthermore, even though greatly distended immediately after obstruction, they appear to be healthy until a few hours before death.

The effects of increasing intra-intestinal pressure following obstructions at the terminal ileum by introducing contents of obstructed bowel into the stomach are not great. Death occurs little sooner than it

does following simple ileal obstruction. At the end of twenty-four hours, the changes of the blood chloride and of the nonprotein nitrogen from the normal are not marked. There is little distention, since the water in the obstructed contents is absorbed.

The difference in the effect produced by introducing the stomach and duodenal contents into the stomach to increase pressure in jejunal and ileal obstructions may be explained by the rapid descent of the contents in ileal obstruction to the jejunum and ileum where they cannot stimulate secretion by irritation of the stomach and duodenal mucosa.

THE THERAPEUTIC VALUE OF SOLUTIONS OF SODIUM CHLORIDE

The intravenous administration of solutions of 5 per cent dextrose or of 0.9 per cent sodium chloride every eight hours after jejunal obstruction lengthens the life of rabbits from two to six hours. There seems to be no difference between the effects of the two solutions as far as survival is concerned. There is with both an increase in the amount of distention due primarily to increased secretion and finally to diminished absorption as distention progresses. The partial correction of the developing dehydration enables the glands of the mucosa to secrete more than when no fluids are given. The harmful effects of the increased intra-intestinal pressure are a little more than offset by the beneficial effects of diminished dehydration. Solutions of sodium chloride seem to have no specific curative effect. The loss of chlorides into the contents

of the obstructed bowel is compensated for by that given intravenously, but the nonprotein nitrogen increases almost as much as when solutions of dextrose are given.

When intra-intestinal pressure is reduced by aspiration or gastrostomy or when all secretions are lost with a jejunostomy, the therapeutic value of solutions of sodium chloride given intravenously or

subcutaneously becomes evident. Life is prolonged from twelve to sixteen hours by the administration of sodium chloride solution at short intervals if the stomach contents are removed every eight hours from an animal with jejunal obstruction. There is less increase in the non-protein nitrogen in the blood than when solutions of dextrose are given.

The difference in value between the two solutions is evident when they are given to animals on which a jejunostomy has been performed.

The duration of life is shorter, and the nonprotein nitrogen is higher when dextrose is administered than when saline is used.

Reduction of intra-intestinal pressure in jejunal obstruction by means of gastrostomy adds considerable operative trauma so that the results are undeterminate. Presumably life would have been prolonged considerably beyond the actual time noted if this trauma had not been added.

The difference of twenty hours in the length of survival of animals suffering loss of both stomach and duodenal secretions as found in those having a jejunostomy, and a loss of only stomach secretions as seen in pyloric obstruction with gastrostomy is evidence that the loss of duodenal secretions is not compensated for by saline. This differ-

ence in survival would probably have been still greater had sufficient sodium chloride been given the animal with pyloric obstruction to maintain the blood chloride at the normal level.

The intravenous administration of solutions of dextrose or of sodium bicarbonate neutralized with lactic acid caused no appreciable changes in the alkali reserve or nonprotein nitrogen of a healthy rabbit.

Sufficient lactic acid to produce noticeable changes in the alkali reserve could not be given without immediately killing the animal.

Solutions of sodium bicarbonate given intravenously in sufficient quantity materially to increase the alkali reserve caused a great increase in the nonprotein nitrogen of the blood.

Comment.—The therapeutic value of the intravenous or subcutaneous administration of solutions of sodium chloride increases as

intra-intestinal pressure is diminished and, conversely, the value decreases as intra-intestinal pressure is increased. The increased supply of fluid enables the animal to increase its gastric and duodenal secretions, thus augmenting distention and diminishing reabsorption unless means are employed to reduce intra-intestinal pressure. The value of sodium chloride lies in the establishment of a normal blood chloride level which corrects alkalosis and thereby lowers the high nonprotein nitrogen.

Life is prolonged most by sodium chloride in pyloric obstructions when gastric distention is prevented by gastrostomy. Here there is loss of gastric secretions of which the chloride is the most important constituent. Replacement of this chloride loss would presumably permit of survival until starvation occurred were it not for the operative trauma. Continued removal of accumulated secretions in the stomach from rabbits with jejunal obstruction and the administration of sodium chloride solutions almost doubles the length of life of rabbits as compared with those having simple jejunal obstruction.

The kidneys show little damage from intestinal obstruction. There is an increased output of urea in the urine during intestinal obstruction as well as the increase in the blood urea.⁶ Evidently catabolic processes are forming waste products more rapidly than normal and more rapidly than the kidney can excrete the accumulating urea. The diminished chlorides may be the cause of this increased catabolism. Presumably there is no appreciable damage to the kidney following twenty-four hour alkalosis induced by the intravenous administration of sodium bicarbonate. The increased nonprotein nitrogen in the blood must then be accounted for by increased catabolism or by abnormal metabolism. The alkalosis accompanying intestinal obstruction may be the cause of part of the increase found in the nonprotein nitrogen. Such an explanation accounts for the rapid decrease in the nonprotein nitrogen found when solutions of sodium chloride are given to correct the alkalosis.

CLINICAL APPLICATION

Rabbits differ from human beings in many respects; nevertheless, certain conclusions seem warranted.

The administration of isotonic or slightly hypertonic solutions of sodium chloride is of great value when measures are taken to insure the least possible increase above the normal intra-intestinal pressure. These measures include the release of the obstruction. The intestinal musculature in human beings does not regain its tone after distention so rapidly as in rabbits, so that simply releasing the obstruction may not reduce intra-intestinal pressure. When the obstruction is high, gastric lavage may diminish pressure sufficiently to restore muscle tone.

6. Haden, R. L., and Orr, T. G.: *Bull. Johns Hopkins Hosp.* 34:26, 1923.

When a large part of the intestine is distended, it must be emptied, preferably by a method causing the least trauma. The intestinal contents need not be removed because of their toxicity, but they must be expelled to relieve pressure. In some instances the intravenous administration of 25 per cent sodium chloride will stimulate peristalsis sufficiently to induce propulsion of intestinal contents and relieve undue pressure. It may be necessary to remove the contents mechanically as by aspiration with trocars at numerous levels. This procedure, in spite of all precautions, is likely to soil the peritoneal cavity and is accompanied by the deleterious effects of trauma. A jejunostomy may be done, not to drain away all the secretions, but to relieve pressure sufficiently to permit of reabsorption of secretions. When intrainestinal pressure is low or has been reduced, it can be kept low by measures that diminish secretion. Large doses of morphine inhibit peristalsis and diminish secretion and thereby aid materially in keeping intra-intestinal pressure low. Such measures will insure the greatest amount of reabsorption of secretions, and thus will aid materially in promoting recovery.

Peritonitis is, in most instances, more dangerous because of the accompanying intestinal paresis than because of the toxicity of infection. Similar methods of treatment are applicable. When there is little distention, the withholding of nourishment by the mouth diminishes secretion. Morphine in liberal doses further decreases secretion so that the limited capacity for absorption is not overtaxed. Solutions of sodium chloride and of dextrose given intravenously restore any deficiency of blood chlorides to normal as well as supply nourishment.

When there is considerable distention, jejunostomy will aid in reducing intra-intestinal pressure. The jejunostomy should be done so as to relieve excess pressure but not to afford complete drainage of gastric and duodenal secretions, for such complete drainage is as disastrous as continued paresis.

SUMMARY

1. Rabbits recover more rapidly from intestinal obstruction if they are permitted to reabsorb the contents of obstructed intestine than when such contents are removed.
2. Diminishing intra-intestinal pressure in obstructed bowel prolongs the life of rabbits, because it diminishes secretions and promotes reabsorption.
3. Increasing the intra-intestinal pressure in obstructed bowel shortens the life of rabbits, because it stimulates secretion and diminishes reabsorption.
4. The therapeutic value of solutions of sodium chloride increases as intra-intestinal pressure in the obstructed bowel diminishes, and, conversely, the value diminishes as intra-intestinal pressure increases.

A COMPARATIVE STUDY OF THE BACTERICIDAL VALUES OF TWENTY-ONE COMMONLY USED ANTISEPTICS *

ABBOTT WILLIAM ALLEN, M.D.

NEW YORK

This paper is the third in a series of studies of antiseptics. The first was a study of the bactericidal effect of mercurochrome-220 soluble¹ on *Bacillus pyocyaneus*, while the second² was an investigation of some of the properties of the antiseptic known as S. T. 37, described in 1927 by Leonard and Feirer.³ The present article is the direct outgrowth of the first two papers, and has for its object a comparative study, in vitro, of the bactericidal effect of twenty-one commonly used antiseptics on four different organisms growing on agar slants.

The organisms used were a freshly isolated strain of *Staphylococcus aureus*, a similar strain of *Bacillus pyocyaneus*, and laboratory stock cultures of *Bacillus subtilis* and *Bacillus typhosus*. Preliminary to the actual experimental work, each culture was transplanted for five successive days on agar slants. Immediately preceding experimentation, two fresh transplants were made from the fifth daily culture to agar slants. These were labeled B and X, while the parent culture was labeled A. Culture X served as a control of growth; A was a twenty-four hour old culture; while B was a freshly inoculated slant. Twenty-one such groups were made up using each of the four organisms employed (fig. 1).

To each of the twenty-one A and B groups of the four cultures, a different antiseptic was added in such quantity that when the culture tube was held in the vertical position, the slant surface was entirely covered by the antiseptic solution, insuring continuous contact of the agar slant surface with its culture and the antiseptic. At intervals of 15, 30, 60 and 180 minutes, transplants were made from the A and B tubes to fresh agar slants A', A'', B', B'', etc. A previously flamed

platinum loop was inserted into the supernatant antiseptic fluid, down to the agar surface, where the loop was drawn across the agar slant surface with its bacterial covering. This loopful of suspension was withdrawn through the antiseptic fluid above and streaked on a fresh agar slant. These tubes plus the originals were incubated at 37 C. for twenty-four hours and then observed. The entire experiment was repeated as a check on the first series.

The antiseptics used were obtained from the hospital pharmacy and conformed to the requirements as indicated in table 1. Dakin's solution was prepared according to the directions of Carrel,⁴ and used the same day. Both Dakin's solution and Zonite were titrated by the method of the same author. The agar was the usual meat infusion agar titrated to a p_H of 7.4.

Of the antiseptics listed, some are used routinely preoperatively, or as prophylactics against infection; others are applied to grossly

Fig. 1.—A diagram showing the origin of the cultures.

infected wounds; those of a third group are employed as antiseptic or germicidal irrigants. In this discussion, no such classification is made. Instead, they are arbitrarily grouped as dyes, halogens, heavy metals, miscellaneous, oxidizers and phenols, according to their exact or most apparent composition (table 2). Obviously, such a classification is approximate at best, and open to criticism. However, this classification with its shortcomings serves the purpose of this paper. It may be remarked in passing that the miscellaneous group should perhaps be called the alcoholic group, since all but one contain a large percentage of alcohol in addition to the other substances present.

This method of determining the bactericidal values of antiseptics is open to criticism. It may be said that it is not a standard method of determining the bactericidal properties of antiseptics. In practice, one

does not routinely or continuously immerse the contaminated or infected field in any antiseptic. Still less is one able to suspend the organisms in the antiseptic as represented by the Rideal-Walker⁵ or the Hygienic Laboratory procedure.⁶

In this work, attention is called to the fact that the penetrating power of each antiseptic was allowed to exert whatever influence it

6. Anderson, J. F., and McClintock, T. B.: A Method for the Bacteriological Standardization of Antiseptics, J. Infect. Dis. 8:1, 1911. Harrington, Charles: Some Studies in Asepsis, Ann. Surg. 40:475 (Oct.) 1904.

amount of the antiseptic was of necessity carried over to the fresh agar slants along with each inoculum of the A', B', etc., tubes.

In practice, one deals with two situations; the one a massive infection characterized usually by pus; the other, mere contamination. The present schema was devised to compare simultaneously, and under as nearly exact conditions as possible, the germicidal effect of the twenty-one antiseptics, under stated conditions, (1) on the type of organism used in determining the phenol coefficient; (2) on three different organ-

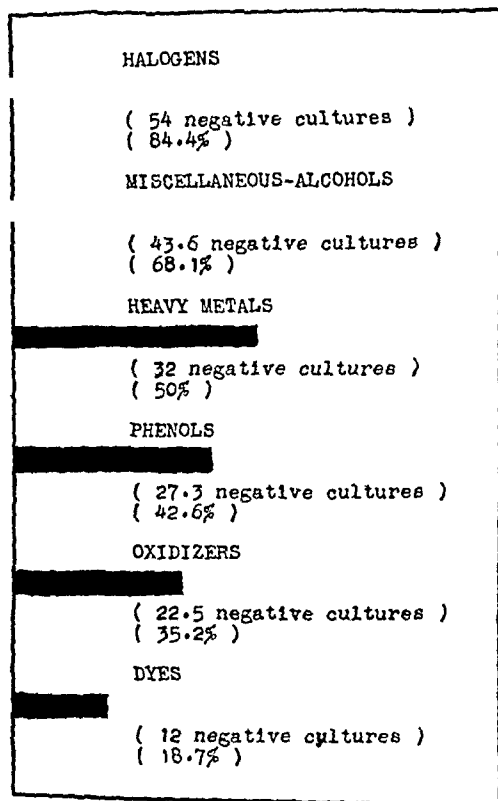

Fig. 2.—A diagram showing the relative efficiency of each of the six types of antiseptics used.

isms, roughly typical of three different classes of invaders; (3) under a condition simulating that most frequently met in routine practice: namely, surface and subsurface massive contamination.

Bacillus typhosus was employed because it is the organism used at present in determining the phenol coefficient of antiseptics. *Staphylococcus aureus* is a common contaminating and infecting organism relatively resistant to antiseptics in vivo, and is roughly characteristic of the pyogenic group. *Bacillus pyocyaneus* is a relatively frequent secondary invader. It is generally more resistant to antiseptics than

TABLE 3.—*The Aniseptics Used, Ranked in Order of Bactericidal Power*

[illegible]

* + Indicates growth of transplant; —, no growth of transplant.

Staphylococcus aureus. It is somewhat typical of the gram-negative bacilli. *Bacillus subtilis*, while not a pathogen, is a spore former, and was used because of that characteristic.

Omitting the control cultures, there were sixty-four transplants of each organism-antiseptic group. Since the negative cultures are indicative of germicidal value, the antiseptics have been listed in descending order of the number of sterile subcultures (table 3). In computing the results for figure 2, the negative cultures of each antiseptic of the six major subdivisions have been totaled and divided by the component number of the group. The percentages expressed are on the basis of sixty-four. From this computation, and also table 3, it is evident that the comparative rating of the antiseptic groups is as follows: halogens, miscellaneous, heavy metals, phenols, oxidizers and dyes.

COMMENT

The value of an antiseptic is commonly expressed in terms of its phenol coefficient. Especially is this true commercially. The bacterium employed in the determination of the phenol coefficient is the *Bacillus typhosus*. Although this procedure is of definite theoretic value, from a practical point of view, it has certain disadvantages. It is known that the organism of typhoid fever has relatively little resistance against many of the commonly used antiseptics. This is well illustrated by the results shown in table 3. If one contrasts the number of positive transplants of the typhoid group with the number of similar subcultures of any other group, it is obvious that the phenol coefficient is at best but superficially relevant to the actual practical bactericidal value of any antiseptic. It is a remote approximation.

CONCLUSIONS

1. The bactericidal efficacy of each of twenty-one commonly used antiseptics was tested against four different organisms.
2. The halogen group, as determined by this study, is the most efficacious of the antiseptic groups.
3. The phenol coefficient value stated as an index of practical bactericidal efficacy is unsatisfactory. The present methods of judging antiseptics do not constitute an accurate index of their practical worth.
4. The need for a comparative study of the bactericidal value of an antiseptic under a variety of conditions before it is offered to the public will be discussed in a later communication.

SURGICAL DISEASES OF THE COLON

COOPERATIVE MANAGEMENT *

FRED W. RANKIN, M.D.

AND

J. ARNOLD BARGEN, M.D.

ROCHESTER, MINN.

The strikingly successful end-results following cooperative management of cases of toxic goiter, of complicated cases of peptic ulcer and of other types of diseases requiring specialized preoperative and postoperative attention find a decidedly suggestive parallel in the group management of surgical diseases of the colon. The combination of resources made available by isolation of patients with surgical lesions of the colon into a single division under the combined management of surgeon and clinician has brought results as striking, in our experience, in the short length of time in which it has been employed, as the results obtained from any segregated group of unusual cases. Not only has isolation of these patients afforded individualization, with better selection of cases for different types of operation, but collective management in the postoperative period has been equally invaluable. Colonic conditions are complicated; they extend over a long period before the patients who suffer from them submit to surgical procedures, and therefore colonic cases have borne not only an unjustifiable surgical mortality but an undeserved reputation for high morbidity and unfavorable prognosis. The grouping of patients with surgical conditions of the colon in a division apart from that of general surgery, and the insistence that their preoperative management be cooperative and directed along distinct lines and that the surgical management at operation be carried out by a small group of surgeons particularly interested in these diseases have, we believe, materially aided us from every standpoint.

During the six months beginning Oct. 1, 1927, and ending April 1, 1928, 147 patients with colonic disease for whom surgical treatment has been prescribed have been isolated in a single section under the medical supervision of A. H. Logan and J. Arnold Borgen, and have been operated on by Walter E. Sistrunk and Fred W. Rankin. Multiple operations were done in practically every instance in this group of cases. In 103 cases two or more operations were performed, and in seven cases as many as four operations. The cases are divided as follows:

* Submitted for publication, Nov. 26, 1928.

* From the Divisions of Surgery and Medicine, The Mayo Clinic.

ninety-four of carcinoma of the rectum, rectosigmoid and sigmoid, five of carcinoma of the descending colon, three of carcinoma of the splenic flexure, five of carcinoma of the transverse colon, one large polyp of the transverse colon, four of carcinoma of the hepatic flexure, six of carcinoma of the cecum, one of carcinoma of the jejunum, three of diverticulitis of the sigmoid with abscess, ten of inflammatory cecal and pericecal lesions, seven of repair of postoperative fistula of the colon, four of resection for rectal stricture, two of closure of colostomy opening made elsewhere, one of resection of a portion of the ileum for obstruction with chronic ulcerative colitis and one of ileosigmoidostomy for a suspected malignant condition following healing chronic ulcerative colitis.

Of the 147 patients operated on, fourteen died, a total mortality of 9.6 per cent. There was only one death from preliminary colostomy in 108 operations; this occurred in a case of inoperable carcinoma of the rectum with obstruction. In the ninety-four cases of carcinoma of the rectum, rectosigmoid and sigmoid there were six deaths following resection, a mortality of 6.47 per cent. Of the fourteen deaths, eight occurred in cases which were pronounced inoperable at the time of exploration.

The preliminary preparation, the change in type of anesthesia and the coordinated postoperative management have resulted in lowering the number of postoperative complications, in the diminution in the number of fatal operative cases and in the application of more radical surgical procedures to the group. One of the most important factors in the treatment in colonic cases is preoperative preparation of the patient by the introduction of rehabilitation measures in addition to the application of local medicaments to the bowel to reduce the virulence of the organisms present and to overcome any obstruction which may have taken place. During the period of preoperative preparation, thorough cleansing of the bowel and filling the patient with foods which have a minimum of residue and may be stored for reserve is essential. The diet consists of a basic allowance of 2,000 calories of carbohydrate, including principally candy and fruit juices. To this, if the patients tolerate it, and the majority do, is added 50 per cent more carbohydrate, making a total of 3,000 calories daily. At ordinary rest, a patient will gain weight on such a diet; yet the bowel will remain comparatively empty. A daily urinalysis is made to note any overflow of the sugar threshold, and the results are checked by a determination of blood sugar which is made at the time of admission and again after a few days on the diet. Sugar rarely will appear in the urine, although there is usually an elevation of the blood sugar within normal limits. Many of these patients are in the later years of life, when tolerance for carbohydrate is more or less reduced; for these patients we have the basic

diet of 2,000 calories of carbohydrate to which is added a variable amount of protein or fat of low residue, or a combination of both. For convenience in calculation we add 25 per cent of fat or 25 per cent of protein, or 50 per cent of either, according to the patient's tolerance. Although the diet is an important factor, both for attaining cleanliness of the bowel and for giving the patient a fighting reserve, other means of emptying the colon have been found expedient. Depending on the amount of obstruction present, castor oil in variable doses of from 30 to 60 cc. is given by mouth in some cases. Twelve hours later, cleansing enemas of a physiologic solution of sodium chloride are given, which are repeated every twelve hours until twenty-four hours before operation. Such preparation takes from three to five days, depending on the amount of obstruction produced by the lesion, its situation in the colon and the general condition of the patient.

If barium has been used in the diagnosis of the lesion of the colon, it must be removed thoroughly. In the diagnosis of lesions of the colon by means of the x-rays, it is more important whenever possible to use thin barium and to wash it out thoroughly by enemas as soon as the roentgen examination has been made. A flat roentgen picture of the abdomen made from twenty-four to forty-eight hours after barium has been given eliminates the danger of sending a patient to the operating table with barium in the bowel. During the first twelve of the last twenty-four hours preceding the first operation, divided doses of camphorated tincture of opium are given by mouth. These serve to allay peristalsis and to quiet the patient in general. Patients are urged to drink much liquid up to twelve hours before operation. During the last twelve hours, the patient is allowed absolute rest; everything is done for his comfort and composure.

The day after the colostomy has been done, irrigations of the lower portion of the bowel which contains the tumor are begun. A physiologic solution of sodium chloride is used, and the irrigations are continued until forty-eight hours before the second stage, or resection. During the last forty-eight hours before the resection, aspiration of the lower segment by section is carried out both from the colostomy opening and from the rectum; it is done several times a day to prepare a dry operating field. The patient again is placed on the carbohydrate diet for twenty-four hours before the resection, and a simple cleansing enema of the portion of the bowel above the colostomy is given the night before operation to prevent gross fecal soiling at the time of operation. Before discontinuing irrigations of the lower portion, the rectum is examined digitally to determine whether or not it is empty.

The patient is observed carefully during the preoperative preparation in an effort to estimate surgical risk and to avoid complications, if possible. Not only is the lesion in the bowel examined carefully by

digital, proctoscopic and, whenever advisable, by roentgenologic methods, but the heart, blood pressure and lungs are carefully examined. Electrocardiograms are made whenever they are thought to be necessary. Renal function is estimated by phenolsulphonphthalein and studies on the blood urea. In older men with hypertrophied prostates and residual urine, particularly if there are rectal lesions, lavage of the bladder is instituted in an effort to avoid an ascending pyelocystitis. A careful note is made of the quantitative output of urine, and particular mention is made of any sign of edema of the extremities. This is especially significant in checking the not infrequent development of postoperative nephrosis. If noted early, the development of this condition into a serious complication usually can be avoided.

An additional measure, which we trust will have an important bearing on the successful management of these cases in the future, is intraperitoneal vaccination against infection of the peritoneal cavity by the use of a mixed vaccine prepared after the methods of Herrmann, who has used it extensively in experimental work. Experience with this type of medication has been too short to warrant an opinion as to its value, but we hope to be able to report more favorably on it in a future communication.

Rehabilitation after resection of a malignant tumor and establishment of colostomy is an important adjunct in the management of the patient. An effort to regulate the time of fecal evacuation from the colostomy opening, as well as to aid the establishment of formed stools by making the patient somewhat constipated, is necessary. The patient is advised, therefore, to eat at regular intervals, to include constipating foods in his diet and to avoid drinking between meals. Another significant consideration is the choice of the colostomy bag. It must be as inconspicuous as possible, should not create a vacuum by its pull on the exposed part of the colostomy, must be easily cleaned and should be relatively inexpensive.

The general acceptance of colostomy for growths in the left colon is perhaps one of the greatest advances in surgery of the colon in the last two decades. Whether the colostomy should be permanent when growths in the upper part of the rectum and sigmoid may be removed safely or whether an anastomosis should be made to reestablish continuity of the bowel is still a question. Although the technical maneuver is feasible, there are surgeons who argue, with considerable logic on their side, that growths in the sigmoid should be treated like growths in the rectum, with colostomy and extirpation of the segment of bowel below it. Usually, in cases in which colostomy is employed, because of the preliminary cleansing of the bowel and irrigation of the local growth to overcome obstruction, we have been able to leave the

bowel intact until the sixth day or longer; then, as gas begins to accumulate and the patient becomes uncomfortable, puncture is made with the cautery to relieve the tension. Subsequently, after healing is insured, the bowel is divided across its entire lumen. Following each operation it has been our custom, satisfactorily carried out, to insist on abstinence from any food or drink by mouth for seventy-two hours or longer. Good evidence that the gastro-intestinal tract is functioning satisfactorily and that infection is not taking place is the patient's ability to expel flatus. After this, administration of liquids by mouth is begun, and gradually the diet is increased. Adequately prepared patients are surprisingly free from gas in the postoperative period, and it is our experience that much of the discomfort following abdominal operations, on both the colon and the viscera, is the result of feeding the patients too early in convalescence. In colonic cases, subcutaneous administration of physiologic solution of sodium chloride or of solution of dextrose (d-glucose) is begun postoperatively, and a continuous flow at the rate of 100 cc. each hour up to 2,000 cc. in twenty-four hours is administered over the necessary period of time. Once the colostomy is done, irrigations are begun through-and-through, so as to alleviate further the local condition and to assist in adequate preparation for the subsequent resection. Usually the interval between the first and second stages of the operation has been from ten to sixteen days.

The selection of the type of operation is not entirely standardized, and the type of operation varies considerably with the half of the colon which is operated on, but the institution of drainage and the principle that most resections of the colon should be graded procedures is unquestionably a step in advance. Although it has been our aim in this group of cases to select the most radical surgical procedure compatible with the general condition of the patient, in the main, graded maneuvers rather than single-stage operation have been done. The graded operation is advantageous from many standpoints and in our hands has been instrumental, we believe, in a most satisfactory lowering of mortality.

To evaluate an aseptic technic for the removal of carcinoma of the colon is difficult. It is only one and one of the least significant steps in the development of surgical treatment of malignant conditions of the gastro-intestinal tract and yet it offers many advantages, and any procedure which accomplishes removal of intestinal carcinoma without opening the intestinal lumen, and with satisfactory functional results, merits consideration. To accomplish successfully a blind resection one must minimize the danger of infection of the peritoneum, which is the main cause of failure in gastro-intestinal surgery, and many simple methods available today emphasize the ease of its accomplishment and make its allocation among other maneuvers more ready.

Each of the two segments of the colon demands a definite technical operation, even though the principle of performing removal of the carcinoma in a graded procedure is adhered to. It has been our custom to attack right-sided colonic carcinomas by first making an aseptic ileocolostomy, and then in about two weeks removing the right half of the colon and from 30 to 35 cm. of the ileum. We believe the end-to-side transplantation of the ileum into the transverse segment of the colon is the most satisfactory type of procedure in this situation, and it can be accomplished easily and with satisfactory functional results by any of the aseptic methods popular today. The dangerous part of this operation is the secondary resection. It, likewise, may be accomplished in a clean manner, but it is more likely to be followed by peritonitis because of contamination from the necessary mobilization of the infected growth.

Colocolostomy or ileocolostomy and subsequent resection of the ascending colon and a portion of the transverse colon is the operation of choice for carcinomas of the transverse colon, unless one resorts to an obstructive operation. The latter type of operation in our service has proved exceptionally useful. We believe that in the majority of cases in which there is little obstruction and in which adequate preoperative measures have been instituted to cleanse the bowel and in this manner to eliminate a certain amount of infection, an obstructive operation may be done. In these cases one may resect the transverse colon or, indeed, any other mobile segment of the bowel and may leave on a clamp much more satisfactorily than by doing the old-time exteriorization procedure of Mikulicz. For this Mikulicz procedure we heartily advocate the substitution either of this obstructive resection or of drainage and at a second stage resection and reestablishment of the continuity of the bowel. On our service, the Mikulicz procedure practically has been abandoned except in a small group of cases of elderly patients who have small, scirrhous carcinomas of mobile segments of the large bowel which readily may be brought outside the abdomen without any preliminary measures of mobilization. In obstructive resection or colostomy and subsequent resection, one avoids the disadvantages of the Mikulicz procedure, for in the former there is no question of implantation of cancer cells in the cut surfaces of the abdominal wound, and more widespread dissection of lymph nodes and removal of the tissues contiguous to the growth is made possible. In cases of carcinoma below the transverse colon and splenic flexure, colostomy and subsequent removal is most advantageous in practically every case. The question of reestablishment of the lumen of the bowel depends on the height of the growth in the left side of the colon. Below the middle of the sigmoid, there is without question a disadvantage in joining again the cut ends of the bowel.

The question of operability, likewise, is not always easy to decide. Obviously, hepatic metastasis rules out radical operation except in an occasional case in which a small growth may be resected, by a simple maneuver, to relieve the patient of a local malignant growth. This happens infrequently and, for all practical purposes, may be forgotten. However, the question of inoperability, because of local conditions attendant on attachment to surrounding structures, is frequently perplexing. If the growth is free and movable and may be removed with or without restoration of the lumen of the bowel, the problem is simple, but if the growth is attached to the parietal peritoneum, to the small bowel or, as it occasionally is, to some other viscus which may be sacrificed without too much operative risk, the question as to the advisability of double resection, or resection and some additional operative maneuver, is not easily answered. More often than not, growths which are attached to the lateral parietal peritoneum have penetrated through the peritoneum and occasionally have formed definite pockets which will be ruptured by the slightest operative manipulation to determine the mobility and fixation of the segment of bowel. Many times we have been driven to resect a growth which had become attached to the parietal peritoneum and which had penetrated, but the penetration was not recognizable until the finger slipped easily into a small pocket during the examination. Mortality is relatively high following this accidental rupture of an abscess because of the direct contamination, and one of the greatest factors in the reduction of operative mortality will be the recognition of growths which are irremovable before some such accidental discovery forces the surgeon to perform resection. Under obstructive conditions the region of the growth becomes highly infective. Infection may take place either from increased permeability of the wall of the bowel or from direct invasion of bacteria through the broken mucosa at and around the large, ulcerating, infected, penetrating and attached growth, which may or may not have an abscess form around it.

Advanced growths which have attending complications due to their fixation, immobility and perforation of the wall of the bowel demand the exercise of meticulous judgment to decide not only whether they are amenable to radical resection but also whether palliative operation is indicated. Fixation in carcinoma of the colon, in the vast majority of instances, is due to inflammatory reactions rather than to direct invasion. The graded operation permits recession of this inflammatory reaction in many instances, with subsequent lessening of the fixation. There is then the likelihood that more radical procedures for removal of the local growth and its offending gland-bearing areas may be instituted with a most satisfactorily small operative mortality.

The choice of anesthetic in colonic cases is not unimportant. Miles, years ago, advocated spinal anesthesia in performing his abdomino-

perineal resection for carcinoma of the rectum, but it has not been universally adopted because of the dislike of general surgeons, as a class, for spinal anesthetization. In our service, during the last two years, we have employed spinal anesthesia as a routine for colostomy and the subsequent resection of all carcinomas of the rectum and for the drainage operation and removal of resectable carcinomas of the colon. The advantages of this procedure have been manifold, and we are convinced that it has had a satisfactory effect on the statistics of immediate operative mortality. Most infrequently we have found it necessary to complement the spinal anesthesia with nitrous oxide, oxygen or ethylene. The only contraindication to the use of spinal anesthesia, to which we have adhered, has been a marked lowering of the systolic blood pressure. The blood pressure is sustained throughout the operation by the administration of ephedrine. Despite an occasional reaction while the patient is on the operating table, we have no inclination to discontinue the use of spinal anesthesia. We feel confident that although the margin of safety may be smaller than that in the routine administration of anesthesia by inhalation, the freedom from pulmonary complications and the relaxation and additional ease in operating warrant the employment of this procedure in this type of case. The operative mortality is necessarily higher in this group than it is in other types of cases, and the risk justifies employment of more radical measures if they are of even slight advantage.

GALLBLADDER

Moynihan¹ found that infection began in the outer coats of the gallbladder in 63 of 81 cases of cholecystitis. In 18, the inner coats were primarily involved. Infection may reach the outer coats by direct extension from the liver, by means of the lymphatics communicating directly between the liver and gallbladder or by involvement of the peritoneal surface as a consequence of disease in an adjacent organ. In cases of infection from within, the ascending route is followed more frequently than is realized. Cholecystitis as a rule is only a part of an infection which has its origin elsewhere. Hepatitis is commonly, if not always, present, and is almost certainly of earlier origin than the inflammation of the gallbladder. Moynihan stated that sufficient regard has not been paid to the spleen as an infective agent. In some cases with recurrent stones and with marked infection in the common bile duct, the spleen may be a causative factor, and splenectomy in such cases may be indicated.

Moynihan stated that the presence of all or most of the symptoms of cholecystitis over a period of weeks or months is sufficient indication for operation. The symptoms, he emphasized, are flatulence and fulness after meals, epigastric discomfort, pain, sudden nausea, acidity, water-brash and sallow complexion. The Graham-Cole procedure is a valuable diagnostic aid, because the concentration of bile has been shown to be checked at times when the external appearance of the viscus is only slightly altered. If inaugural symptoms are present and the cholecystographic shadow is absent or delayed, operation may be performed.

* Submitted for publication, May 7, 1929.

1. Moynihan, Berkeley: Mitchell Banks Memorial Lecture on the Gall-Bladder and Its Infections, Brit. M. J. 1:1, 1928.

Moynihan many times has hesitated to take the gallbladder out in cases of inveterate mild dyspepsia; when he has not done so, he has been compelled to operate later and has had good results. He was of the opinion that the gallbladder should be removed more frequently than is now being done.

Wilkie² of Edinburgh also stressed the importance of early surgical intervention in disease of the gallbladder. In cases of flatulent dyspepsia, in which the gallbladder seems implicated, he advised removal.

[COMPILERS' NOTE.—Recent studies of the functions of the gallbladder demonstrate that it is not merely a vestigial organ, and although its loss is well tolerated in man, we believe that the best indication for its removal is the clinical history and especially the presence of colic. Patients who give such a history usually will be relieved of symptoms by removal of the gallbladder even in the absence of any grossly demonstrable pathologic lesion. Patients with symptoms of mild dyspepsia and indefinite complaints relative to the upper part of the abdomen are not always cured by removal of a gallbladder which appears normal. The Graham-Cole procedure is a good diagnostic aid, but it should not be used as an indication for cholecystectomy in the absence of a good clinical history of disease of the gallbladder. We believe, as Moynihan and Wilkie have indicated, that the best results are obtained by operating as soon as the diagnosis is made.]

Wilkie,³ in an experimental study, concluded that infection in the gallbladder precedes the common hepatic changes seen in cholecystitis. He interposed omentum between the liver and gallbladder in rabbits and produced cholecystitis by injecting streptococci obtained from cystic lymph glands of man which drained diseased gallbladders. In cases in which the omentum had been interposed between the gallbladder and liver, the liver remained grossly and microscopically normal. In the control animals, definite localized hepatitis was produced.

[COMPILERS' NOTE.—More or less well defined localized hepatitis is such a constant occurrence in cholecystitis that its presence may be used as an indication of disease of the gallbladder even in the absence of marked pathologic changes in the gallbladder itself. We are, nevertheless, inclined to the view that the primary lesion is most often in the gallbladder, and that the localized hepatitis is secondary.]

Illingworth,⁴ in 100 cases in which operation had been done, noted the frequency of intramural infection of the gallbladder and that sterile bile rather commonly is found. He concluded that cholecystitis is a

blood-borne infection and that ascending infection, or infection from the liver, is the exception rather than the rule.

Bacteriology.—Wilkie⁵ concluded that cholecystitis is a blood-borne streptococcic infection of the walls of the gallbladder. He made cultures of the whole thickness of the wall of the gallbladder and found that growth did not result as a rule, whereas cultures from the submucosa and outer coats, leaving the mucosa intact, gave growths of streptococci in 42 per cent of cases. Bile inhibited the growth of streptococci. The cystic lymph node in cholecystitis gave a growth of streptococci in 86 per cent of cases.

In only 6 per cent of cases was *Bacillus coli* recovered from bile; in only one case was it recovered from the cystic lymph node and in this case probably there was contamination from bile.

A suspension of streptococci in physiologic solution of sodium chloride was injected into the lumen of the gallbladder in rabbits and did not produce change. However, intramural injection of the suspension produced progressive chronic cholecystitis, and the organism readily was recovered. Intramural injection of the suspension of streptococci, after the cyst duct was ligated, produced chronic empyema with marked intramural changes. Calculi were produced in both types of intramural injection. Repeated intravenous injections of the streptococci gave progressive chronic cholecystitis with formation of cholesterol stones. Intramural infections of the gallbladder without ligation of the cystic duct produced only stones of cholesterol, but when the cystic duct was ligated, the stones produced were of calcium and cholesterol. The intramural injections gave pathologic changes which resembled in every way those found in diseased gallbladders in man.

Wilkie² emphasized the importance in making bacteriologic studies in disease of the gallbladder of making cultures from the cystic lymph node at the neck of the gallbladder. In 100 cases of disease of the gallbladder including early cases with practically no change in the appearance of the gallbladder, 84 cystic lymph nodes gave a pure culture of streptococci.

[COMPILERS' NOTE.—One cannot draw definite conclusions as to the rôle played by bacteria in producing cholecystitis by bacteriologic studies of the gallbladder and bile. Judd, Mentzer and Parkhill,⁶ in 200 cases, obtained 14 per cent of positive cultures from the bile of the gallbladder. Positive cultures were most frequently obtained from light colored, grainy, purulent or blood-tinged bile. Bile of normal appearance,

including concentrated dark bile, was usually negative. Forty-nine per cent of positive cultures were obtained from the wall of the gallbladder and 31 per cent from gallstones. Rosenow, many years ago, obtained a much higher percentage of positive cultures. This may be due to the fact that chronically diseased gallbladders were not removed as frequently then as now.]

Etiology.—Sherwood⁷ reviewed a series of 200 consecutive cases of diseases of the biliary tract occurring in the last four years. The pathologic material included other cases in the same hospital studied by Denton. He examined 400 gallbladders and characterized the lesions of the biliary tract as primarily mechanical and circulatory rather than infectious disturbances.

In Sherwood's experience, by far the greater number of disturbances of the biliary tract which may be treated successfully by the surgeon, with the greatest relief and satisfaction to the patient, are those which have their basis in obstruction to the normal flow of bile through the system of ducts. The most common cause of obstruction is the presence of stones. Stones in the extrahepatic ducts are the most serious, the gravity of the condition depending on the completeness of the occlusion. The presence of stones in the gallbladder may or may not be accompanied by symptoms or appreciable pathologic changes. Such stones often appear to be harmless foreign bodies although invariably they are a potential source of trouble and danger. Cultures made from freshly removed gallbladders which contained stones frequently gave negative results, and sections of the walls of the gallbladder did not reveal any of the characteristic changes associated with infection. On the other hand, when pathologic change is easily recognizable, such changes appear to be the result of mechanical and circulatory disturbances. That secondary infection may and often does develop as a result of the presence of stones is not denied. Sherwood believed that a disturbance or unbalance of chemistry in the body, particularly in its relation to cholesterol and metabolism of calcium, must be a significant and primary factor in the etiology of cholelithiasis.

Patients who obtained the most permanent and complete relief following operation were those with cholelithiasis who sought relief because of repeated attacks of biliary colic or because of an acute attack characterized by severe pain in the right upper quadrant of the abdomen. At operation in these cases it was found that almost invariably they were associated with impaction of a stone in the cystic or, more rarely, in the common duct; the underlying pathologic changes were due to mechanical and circulatory disturbances rather than to infection. When infection was present, it seemed to be a complication.

7. Sherwood, W. A.: Surgical Lesions of the Biliary Tract, *Ann. Surg.* 88:178, 1928.

The patients with the least satisfactory results in relief from symptoms were those without stones, who sought relief not because of severe pain or colic but because of vague digestive disturbances, and who did not have more definite pathologic changes than slight fibrosis or involution atrophy. Such changes are the same as may be seen in many other tissues and organs in patients after middle age. Sherwood expressed the belief that such gallbladders should be less frequently removed than has been the practice in many clinics, and that causes for such symptoms should be sought elsewhere. The word, cholecystitis, implies the presence of infection, and Sherwood asks if it always portrays an accurate picture of the most frequently encountered and predominant surgical lesions of the gallbladder.

[COMPILERS' NOTE.—For many years we have been under the impression that not all cases of disease of the gallbladder are due to bacterial infection. A number of years ago, while observing the effects of the intravenous injection of surgical solution of chlorinated soda (Dakin's solution) in animals, Mann was surprised to note its apparent selective affinity for the gallbladder and the production of cholecystitis indistinguishable pathologically from certain cases of chronic cholecystitis in man. This, and more recent studies by Mentzer⁸ and others, have led us to believe that certain groups of diseases of the gallbladder are due to chemical or metabolic disturbances. This view is strengthened by the belief that cholecytic disease is often not a disease of a single organ but of a system and of each person.]

Lyons and Swalm⁹ expressed the belief that many cases in which a positive cholecystogram is obtained by the Graham-Cole method and in which, at operation, a pathologic lesion of the gallbladder is not found, are due to an obstructive catarrhal condition of the cystic duct, which will respond to nonsurgical drainage, which will remain normal and which will give a negative cholecystogram. This is particularly true in cases of low-grade cholecystitis. There is no definite symptomatology in this form of obstruction of the cystic duct and it can be diagnosed only by studies of biliary drainage.

Diseases of the Gallbladder in the Young.—Potter¹⁰ found that pathologic lesions in the biliary tract are much more common in young persons and children than is generally recognized. He reviewed

8. Mentzer, S. H.: Cholesterosis of the Gallbladder, *Am. J. Path.* **1**:383, 1925; A Clinical and Pathologic Study of Cholecystitis and Cholelithiasis, *Surg. Gynec. Obst.* **42**:782, 1926; The Pathogenesis of Biliary Calculi, *Arch. Surg.* **14**:14 (Jan.) 1927.

10. Potter, A. H.: Gallbladder Disease in Young Subjects, *Surg. Gynec. Obst.* **46**:795, 1928.

226 cases from the literature and added 4 of his own in which disease of the biliary tract existed in children up to 15 years of age. He cited 2 cases of stones in the common duct in fetal life (6 and 8 months, respectively). In the entire series, gallstones were present in 140 cases, cholecystitis with stones in 44 cases, cholecystitis without stones in 59 cases and cholecystitis with jaundice in 30 cases. Stones in the cystic duct were found 14 times; in the common duct, 13 times. Hydrops of the gallbladder was found 18 times and infection of the gallbladder 43 times. There were 2 cases of malignant disease of the gallbladder in patients aged 4 and 15 years, respectively. Acute cholecystitis is relatively common in the series.

Potter believed that etiologically, and in order of their importance as causative agents in diseases of the gallbladder, are the following: influenza, appendicitis, scarlet fever, diphtheria and infections of the digestive tract regardless of origin.

Operations.—DeCourcy¹¹ reported a series of 400 operations on the gallbladder in which cholecystectomy yielded better operative results than cholecystostomy. He reviewed this subject and found that, in general, recognition is given the fact that symptoms are only too likely to persist after simple drainage of the gallbladder, even if there is no actual recurrence of the disease. Furthermore, an infected gallbladder, if allowed to remain within the abdominal cavity, is a menace to the security of the biliary ducts, pancreas, liver, duodenum and organism as a whole.

[COMPILERS' NOTE.—In most surgical clinics, cholecystectomy is now performed in preference to cholecystostomy in cases of chronic cholecystitis. Concerning the treatment for acute cholecystitis, there is not very uniform agreement. We prefer, whenever possible, to let the acute condition subside and then to remove the gallbladder. Cholecystostomy is done only when some particularly difficult technical procedure presents itself or the poor condition of the patient demands the least dangerous operation. In some jaundiced patients, also, it is advisable to leave in the gallbladder, as it may be useful later if a condition arose which necessitated an anastomosis between the biliary and the intestinal tracts.]

Pribram¹² reported a procedure he had used in about 200 cases of cholelithiasis, which has been successful in the most complicated and difficult cases and which has permitted him to carry out the principle of abdominal closure without drainage. The reasons which usually have

11. DeCourcy, J. L.: Cholecystectomy or Cholecystostomy? *Internat. J. Med. & Surg.* 41:426, 1928.

12. Pribram, B. O.: Mukoklase und drainagelose Gallenchirurgie, *Zentralbl. f. Chir.* 55:773, 1928.

been given against closure without drainage are the danger of a ligature slipping off the cystic duct, secondary hemorrhage and drainage of bile from the hepatic surface. The last mentioned complication is the one most frequently encountered. To avoid this complication, Pribram carries out the following technic: The gallbladder is first drained of all bile by means of suction, and with scissors a longitudinal slit is made in the gallbladder from the fundus to the cystic duct; all stones are removed; the exposed cystic duct is now cut between two ligatures, the mucous surfaces of the gallbladder then are charred by means of the actual cautery and any small hepatic abscesses lying behind the gallbladder are likewise destroyed; cauterization extends through to the serosa of the gallbladder; the two cauterized flaps of the gallbladder are then inverted into the fossa of the gallbladder and the serosal surfaces of the gallbladder are sutured over the fossa.

The method is recommended for those cases of cholecystic disease in which subserous extirpation of the gallbladder is technically impossible because of inflammatory changes in the wall. Raw surfaces in the fossa of the gallbladder thus are eliminated.

Biliary-Intestinal Anastomosing Operations.—Judd and Parker¹³ studied 137 consecutive cases in which anastomosis of the biliary and gastro-intestinal tracts was carried out from 1919 to 1924. There were 34 cases of carcinoma of the pancreas. Contrary to the general teaching, colic with jaundice occurred in 35.29 per cent of these cases, pain with jaundice in 23.52 per cent and colic, pain and jaundice in 2.94 per cent. Thus colic or pain, or both, with jaundice occurred in 61.75 per cent and jaundice without pain in only 38.23 per cent of cases. Intermittent jaundice occurred in 5 of the 12 cases with colic alone. Gallstones were found in only 1 case. Cholecystogastrostomy was the operation of choice in this group, and was performed in 26 of the 34 cases. The average postoperative duration of life was 7.7 months. The relief from jaundice in patients who survived operation was complete and permanent in 63.63 per cent of cases.

Carcinoma of the biliary ducts occurred 9 times in the series. The lesion was situated at the ampulla in 6 cases. Colic with jaundice occurred in 22.22 per cent, pain with jaundice in 44.44 per cent and jaundice without pain in 33.33 per cent of cases. Cholecystogastrostomy was the operation of choice. The average postoperative duration of life was 12.2 months.

There were 14 cases in which it was impossible at operation to determine if the lesion was carcinoma of the pancreas or pancreatitis.

13. Judd, E. S., and Parker, B. R.: Biliary Intestinal Anastomosis for Obstructive Jaundice: Analysis of 137 Consecutive Cases, *Arch. Surg.* **17**:1 (July) 1928.

In this group jaundice without pain was present in 71.42 per cent of cases. Cholecystogastrostomy was again the operation of choice. Of this group, 4 patients are alive; 2 have lived six years; 1, more than three years, and 1 for one year. Eleven cases of pancreatitis are reported. Of these, 6 patients had pain and colic, and 5 did not have pain or colic.

There were 62 cases of stenosis of the biliary ducts. All but one of these patients had been operated on previously. This patient had acute cholecystitis with stones and a dense cicatricial stricture of the duct. In some patients, the trouble appeared immediately after operation, and in others obstructive symptoms did not occur until a number of months following operation. In several cases the stricture probably was due to continuation of the inflammation of the biliary duct, obliterative cholangitis. Pain and colic were common symptoms. In only 3 cases there was no jaundice; in all the others intermittent jaundice of some degree was present. Hepaticoduodenostomy was the operation of choice. Seventeen patients are living and cured more than five years postoperatively; 16 are greatly improved from two to six years postoperatively; 9 are in only fair health; 2 have occasional attacks of pain, chills with fever and jaundice, but little dyspepsia. Partial or complete contraction of the stoma occurred in 7 of the 47 cases in which hepaticoduodenostomy had been performed for stricture. Return of symptoms occurred from one to six months postoperatively. Reconstruction over a tube was carried out in each case. Six patients survived operation; 2 are completely relieved of symptoms three and a half and four years postoperatively; 3 are much improved. One patient, who apparently was recovered from biliary obstruction, died one and a half years after operation from acute gastric obstruction.

Drainage.—Richter and Zimmerman¹⁴ have closed the abdomen without drainage in operations on the gallbladder for over twelve years and are convinced of the safety and of the advantages gained in omitting the drain. They also close without drainage after work on the common duct and after transduodenal choledochotomy as well as after simple cholecystectomy. They usually follow this practice in acutely infected cases as well as in chronic cases and in relatively aseptic cases. They do not regard the spilling of bile or of duodenal contents in the field of operation as a contraindication to primary closure. If there is uncontrollable oozing, or if in operations on the common bile duct accurate closure of the duct is not possible or some other special contraindication exists, drains are used. Richter and Zimmerman have made primary closure in 262 operations on the biliary tract.

14. Richter, H. M., and Zimmerman, L. M.: Closure of the Abdomen Without Drainage After Operations Upon the Bile Ducts, *Ann. Surg.* 88:187, 1928.

Their report is based on 418 operations done in consecutive cases of disease of the biliary tract. Cholecystectomy was done in 323 cases 65 times with additional work on the common duct and 25 times associated with some other major abdominal surgical procedure. In the 232 operations of cholecystectomy, the wound was drained in 70 and closed primarily without drainage in 253 cases. Simple cholecystectomy with primary closure was done 204 times with 2 deaths, an average mortality rate of 0.98 per cent. One death was due to acute pancreatitis, the other to pulmonary embolism. The average mortality in all the cholecystectomized cases, including those with work on the common duct, or other major operative procedures, was 3.39 per cent. The percentage of fatalities is higher in the groups in which drainage was allowed than in those in which it was not provided for; the explanation is that the most difficult cases are those in which drainage most often is required. The common bile duct was operated on 84 times in this series: in 55 cases with drainage and in 29 with primary closure. Of the group of 55 patients, 10 died, and there were 2 deaths in the 29 cases without drainage. There were 23 deaths in the entire series, an operative mortality of 5.5 per cent. Sixteen of the 23 deaths were in cases in which drainage was allowed, whereas only 7 deaths occurred in the cases without drainage. Among the cases in which drainage was not instituted there was only 1 death from peritonitis. In this case cholecystectomy and transduodenal exploration of the common bile duct was done.

The advantage of omitting the drain is that the postoperative discomforts are minimized, the incidence of infection and hernia is less and the period of convalescence is shortened. The frequent escape of bile seen after operation in which the incision is drained is not seen if the drain is omitted. Two cases are cited in which operation was done elsewhere; because of technical errors a large amount of bile accumulated in the abdominal cavity, remained some time and apparently was well tolerated.

Wangensteen,¹⁵ as a result of an experimental and clinical study and an extensive review of the literature pertaining to the question of drainage in operations on the gallbladder, concluded that all wounds in cholecystectomy should be drained.

[COMPILERS' NOTE.—While certain rules can be laid down for either draining or not draining in surgical cases, in the final analysis the question remains one for each surgeon to decide from his own experience. We have closed the abdominal wound without drainage in a number in which cholecystectomy was performed. Each case must be decided indi-

15. Wangensteen, O. H.: Should the Gall-Bladder be Removed Without Drainage? *Ann. Surg.* 84:821, 1926.

vidually, and if the drain safely can be omitted, we find that the patient has a smoother and more rapid convalescence. We always institute drainage after surgical procedures on the common bile duct.]

Anomalies.—Bower¹⁶ reported a case of a man, aged 50, who was operated on because of severe pain in the upper right portion of the abdomen. The diagnosis was acute pancreatitis or perforated duodenal ulcer. At operation, the liver was found to be entirely without a left lobe and a gallbladder or fissure was not present; extrahepatic ducts could not be definitely demonstrated. The head of the pancreas was swollen and firm.

An abstract of previously reported cases is given, which included 13 cases of absence of the gallbladder and all ducts, 14 cases of absence of the gallbladder, cystic and common bile ducts and 31 cases of absence of the gallbladder and cystic duct. Other anomalies are also briefly discussed.

[COMPILERS' NOTE.—We have seen a case of congenital absence of the gallbladder which was discovered at necropsy in a patient who during life had not had manifestations of cholecystic disease. The common duct was only slightly larger than normal. At operation, one sometimes has to search carefully for a gallbladder which has been totally destroyed as a result of chronic inflammation. Often only a little bit of shrivelled scar tissue remains.]

Cholecystography.—Dick and Wallace¹⁷ presented two cases with untoward reactions following the intravenous injection of sodium tetraiodophenolphthalein for cholecystography. In one, acute hemorrhagic pancreatitis followed immediately the injection of the dye. In another, jaundice developed following the use of the dye, and in a third case death resulted from the oral administration of the dye in a young jaundiced patient.

Experimentally, normal bile to which sodium tetraiodophenolphthalein was added was introduced into pancreatic ducts and it produced acute pancreatitis. From this it might be inferred that in the presence of a stone of the common bile duct a similar reflux into the pancreatic ducts of bile containing the salt might occur and cause pancreatitis. In cases of obstructive jaundice, small quantities of sodium tetraiodophenolphthalein were found in the pancreatic juice, and from this Dick and Wallace concluded that injury to the pancreas is possible when the dye is used in cases of obstructive jaundice. They believed

16. Bower, J. O.: Congenital Absence of the Gall-Bladder, *Ann. Surg.* **88**:80, 1928.

17. Dick, B. M., and Wallace, V. G. H.: Cholecystography: Toxic Effects of the Dyes: A Clinical and Experimental Study, *Brit. J. Surg.* **15**:360, 1927-1928.

that in the presence of the hepatic injury that is found in obstructive jaundice, the dye is more toxic in its effect than when the livers are not so injured.

[COMPILERS' NOTE.—Mild untoward reactions such as nausea, vomiting and purging occasionally follow the administration of the salts of bromine and iodine used in cholecystography. Severe reactions fortunately are rare. Kirklin and Kendall¹⁸ have recently prepared a new compound, di-iodo-di-ethyl-ether of di-salicylphthalein, which is administered orally in the form of a 10 per cent aqueous solution of its sodium salt. The drug is less toxic than those in general use.]

FALCIFORM LIGAMENT

Schmieden and Peiper¹⁹ studied the development, comparative anatomy, histology and pathology of the ligamentum teres hepatis. They found that it reaches its highest state of development in man. It is not a suspensory ligament of the liver, but together with the lateral umbilical ligaments and the fascia umbilicalis, all of which are closely interwoven in the region of the umbilicus, the falciform ligament forms a support for the anterior abdominal wall. The ligamentum teres hepatis contains a number of blood vessels and lymph channels and also a great deal of smooth muscle and apparently is capable of lengthening and shortening under nervous control, although this has not been definitely demonstrated. The authors have seen two cases in which pathologically produced shortening of the ligament caused symptoms in the upper part of the abdomen which were relieved by dividing it. They were of the opinion that this shortening is due to a chronic inflammatory process. The ligament furnishes a bridge between the retroperitoneal tissues and the anterior abdominal wall. In acute pancreatitis, it is often endematous and contains areas of fat necrosis. It is suggested that the umbilical colic in appendicitis in children may be due to spasm of the smooth muscle of the ligament.

The falciform ligament also is important as a pathway for the spread of carcinoma. Metastasis has been found in the ligament in carcinoma of the stomach and liver. Together with the umbilical ligaments, the falciform ligament may furnish the route by which carcinoma of the rectum metastasizes to the liver. In primary malignant tumors of the umbilicus, as much of the ligament should be excised as possible. The vessels of the ligamentum teres hepatis form an anastomosis with those of the abdominal wall on one side and with the portal

19. Schmieden, Viktor, and Peiper, Herbert: Die Chirurgie des Ligamentum teres hepatis, *Arch. f. klin. Chir.* 152:393, 1928.

vein on the other. This is of significance in cirrhosis of the liver, and Talma's operation, therefore, should be done not above but below the umbilicus in order to avoid interfering with the natural compensatory circulation furnished by the ligamentum teres hepatis.

[COMPILERS' NOTE.—The falciform ligament has wide normal variations in form, structure and vascularity. We never have hesitated to divide the ligament when doing so would give better exposure of the field of operation. The advantages of dividing it are particularly evident in operations on the biliary tract. We have always been careful to reunite the cut ends of the ligament before closing the abdominal wound and are not aware of any ill effects resulting from this procedure.]

PANCREAS

Schmieden and Sebening²⁰ reviewed a series of 1,510 cases of acute pancreatic necrosis occurring since 1918. In this series, 980 cases were in women and 520 in men. Operation was performed on 1,278 patients. There are numerous theories as to the cause of acute pancreatitis, but diseases of the biliary tract are of greatest significance in its etiology. Of 1,278 cases in which operation was performed for acute pancreatic necrosis, there was disease of the biliary tract in 894 (69.8 per cent). In 31 cases of acute pancreatitis associated with gallstones the authors found stones in the ampulla in 7. Schmieden and Sebening reported 38 cases of pancreatitis after operations on the biliary tract, of which 24 followed cholecystectomy. A preoperative diagnosis of pancreatitis is not often made. The diastase reaction of Wohlgemuth is of diagnostic value. A correct diagnosis was made in 21.8 per cent and a probable diagnosis in 17.5 per cent of all the patients operated on. The incorrect diagnosis most frequently made was acute cholecystitis.

Early operation is imperative, as 95 per cent of patients not operated on die. In Schmieden and Sebening's series, the operative mortality was 51.2 per cent. In addition to instituting drainage, significant lesions of the biliary tract should be remedied. In the patients who recover from the operation, the prognosis is good. Of 624 patients who lived, only 26 had recurrences. There may be a temporary diminution in dextrose tolerance; diabetes followed in 18 cases of this series. In 6 cases, chronic pancreatitis developed.

Chronic pancreatitis is generally a medical problem. The condition is hard to recognize even with the abdomen open, as the size and consistency of the gland vary greatly under normal conditions and during different phases of digestion. It is difficult to distinguish pancreatitis from carcinoma. Of a series of 308 patients, 127 had jaundice.

20. Schmieden and Sebening, W.: *Chirurgie des Pankreas*, Arch. f. klin. Chir. 148:319, 1927.

A series of 20 cases of pancreatic stones is reported, 11 of which were removed at operation. All these patients recovered. Of the 20 cases of pancreatic stones, only 2 were demonstrated by the roentgen rays. One hundred and twenty-eight pancreatic cysts are reported, most of which were drained to the outside; a few showed anastomosis to the gallbladder or intestinal tract. Operation in traumatic injury of the pancreas aims to convey the secretions to the outside.

Coenen²¹ has interested himself in a clinical investigation to determine in which cases of acute pancreatic necrosis drainage of the common bile duct, without incision and drainage of the pancreas, is indicated. Unfortunately, the anatomic and physiologic relationship of the biliary and pancreatic ducts is not such that in the majority of cases the toxic syndrome of pancreatic necrosis can be attributed to the presence of bile in the pancreas. Coenen expressed the belief that the common bile duct should not be drained primarily in every case of acute pancreatitis, since this method would bring relief only in those cases in which the pancreatic necrosis originated from the penetration of bile into the pancreatic system. Pancreatitis originating in other ways would not be affected by drainage of the choledochus.

In acute pancreatitis any unnecessary delay in instituting a surgical procedure may seriously handicap the chances of a patient's recovery. Free incision of the diseased pancreas and drainage with gauze strips and rubber tubing are of value in acute pancreatitis.

An absolute indication for drainage of the choledochus may be said to exist, if on examination of the biliary system an associated cholecystitis and cholelithiasis is found to be present. A relative indication for drainage of the choledochus exists if the common bile duct is dilated, or if cloudy bile is aspirated from the common bile duct in cases of pancreatic necrosis. In cases of traumatic pancreatic necrosis drainage of the common bile duct should be instituted only when the common duct is injured.

Grassberger²² studied quantitatively the pancreatic ferments in the blood in diseases of the pancreas, paying especial attention to those patients with gastric or duodenal ulcer penetrating into the pancreas. He investigated especially the atoxyl resisting lipases which are specific to the pancreas. There is no method as yet for differentiating the diastase of the pancreas from that of the salivary glands. Grassberger showed that pancreatic ferments in the blood vary but little under normal conditions and after operations on abdominal organs other than the

22. Grassberger, A.: Fermentuntersuchungen im Blut bei Pankreaserkrankungen mit besonderer Berücksichtigung des in das Pankreas penetrierenden Magen-Duodenalulcus, *Deutsche Ztschr. f. Chir.* **210**:293, 1928.

pancreas. In a series of gastric and duodenal ulcers, he was unable to determine whether or not they had penetrated into the head of the pancreas by a study of the ferments in the blood. In acute disease of the pancreas superimposed on a chronically diseased organ there is an increase in the pancreatic lipases in the blood.

Bernhard²³ was able to demonstrate hyperglycemia in pancreatic diseases. In mild cases, 50 Gm. of dextrose is given by mouth and even those patients with only slight pancreatic necrosis showed a delayed curve of blood sugar. The method is of value in distinguishing between disease of the biliary tract and pancreas in certain mild, obscure cases. The hyperglycemia is due probably to decreased production of insulin, and the administration of insulin to the patient is indicated. Bernhard was of the opinion that diseases of the pancreas are a more frequent cause of symptoms referable to the upper part of the abdomen than is generally realized.

[COMPILERS' NOTE.—The diagnosis of chronic pancreatitis, even with the abdomen open, is not always easily made, nor can its degree be accurately measured. Chronic pancreatitis does, however, occur frequently in association with chronic cholecystitis and seems to be a frequent cause of the continuation of symptoms following cholecystectomy. Patients with pancreatitis may continue to have symptoms for from several months to a year or more after operation. In giving a prognosis, it is important to bear this fact in mind.

In excising a gastric ulcer that is adherent to the pancreas, or in doing a resection for gastric ulcer or carcinoma of the stomach, we frequently have been forced to resect a small portion of the pancreas. Occasionally when this has been done a little pancreatic fluid will drain for a time. In all our cases, however, healing has been spontaneous and there have been no untoward effects.

The problem presented by acute pancreatic necrosis is by far the most serious one in diseases of the pancreas. Early operation is imperative, a procedure which sometimes is handicapped by the difficulty in making the diagnosis. Occasionally a true pancreatic abscess forms which may work its way to the anterior abdominal wall. We have seen this occur preoperatively and also following operations on the biliary tract.]

SPLEEN

Spence²⁴ suggested that purpura hemorrhagica is a disease of the whole reticulo-endothelial system and that three different types exist depending on the part involved and the extent of involvement. Splenec-

23. Bernhard, F.: Ueber die Hyperglykaemie bei akuten Pankreaserkrankungen, *Deutsche Ztschr. f. Chir.* **212**:209, 1928.

24. Spence, A. W.: The Results of Splenectomy for Purpura Haemorrhagica, *Brit. J. Surg.* **15**:466, 1927-1928.

tomy, it is known, brings about a cure in some types of purpura hemorrhagica, and in other types it is not of value. This may be explained by the fact that probably the underlying pathologic cause is elsewhere in the reticulo-endothelial system and not in the spleen in these cases in which splenectomy is not of benefit.

The three types described by Spence are: first, those in which the whole reticulo-endothelial system is uniformly affected. The diseased megakaryocytes produce defective platelets which are destroyed in excess by a diseased spleen as well as by the remainder of the reticulo-endothelial system. In these cases, splenectomy gives poor results. The second type are those cases in which the spleen is chiefly affected and the platelets are destroyed by the diseased spleen. Compensating for this rapid destruction of platelets, the megakaryocytes are overworked and are stimulated to produce defective platelets. When the spleen is removed, the rapid destruction of platelets ceases and the bone marrow is enabled to recover and to produce normal platelets. In this type, splenectomy is of great service. The third type are those cases in which the injury is to the bone marrow and extrasplenic reticulo-endothelial system rather than to the spleen. Obviously, splenectomy in this type is useless.

Green²⁵ stated that splenectomy for thrombocytopenic purpura hemorrhagica is a purely empiric procedure and is based on the knowledge that splenectomy produces an increase in the blood platelets or thrombocytes. Investigators have shown that splenectomy causes this increase of platelets immediately, and in large numbers, and that they appear in increasingly greater numbers each day, reaching their greatest height from the tenth to the fourteenth day. Following this they subside to the normal figure in from three to four weeks. Little is known of the etiology or pathology of thrombocytopenic purpura, and differentiation from other diseases of the blood is often difficult. Werlhof first separated purpura hemorrhagica from other hemorrhagic diseases in 1731.

The essential characteristics of purpura hemorrhagica are: marked decrease of platelets, normal coagulation time, delayed bleeding time, no retraction of the clot and no variation in the cellular elements of the blood. Unless these factors can be demonstrated, one should hesitate before calling a given condition purpura hemorrhagica and splenectomy should not be done.

Brill and Rosenthal first associated thrombocytopenic purpura with the reticulo-endothelial system. The cells of this system are found in the blood sinuses of the spleen, the sinuses of the lymph nodes, the

25. Green, T. M.: Splenectomy for Thrombocytopenic Purpura Hemorrhagica, *Internat. J. Med. & Surg.* **41**:487, 1928.

capillaries of the hepatic lobules and in the capillaries of the bone marrow. Some of these cells also are observed wandering throughout the connective tissues of the body and also, clustered about the capillaries. These cells are known as Rouget cells and seem to exert definite control over the passage of the cellular elements of the blood through the capillary wall.

In 1916, Kaznelson advocated splenectomy for this condition on the assumption that the disease was due to excessive destruction of the blood platelets from overactivity of that portion of the reticulo-endothelial system situated within the spleen. When other portions of this system are at fault, as in Gaucher's disease, splenectomy is useless since the affected part of the reticulo-endothelial system lies within the lymph nodes and bone marrow. Focal infection has been given as a causative factor in the dysfunction of the reticulo-endothelial system. In the application of the tourniquet, petechiae do not appear in acute cases and do appear in the chronic cases. The bleeding is usually capillary and, when visible, is in the nature of oozing from the gums, the nose, the uterus, the bowel and the kidney. Treatment consists of transfusion and splenectomy, neither of which is aimed at the true etiology. Transfusions are repeated during the acute stage and splenectomy is considered only when the disease becomes chronic. Irradiation with ultraviolet rays, in the author's opinion, is not of value. Green reported a case of thrombocytopenic purpura successfully treated by repeated transfusions and splenectomy.

Anschütz²⁶ observed that the prospects for cure by splenectomy in cases of chronic essential thrombopenia are satisfactory in the few cases studied, especially when the blood platelets remain high. Splenectomy in cases with low platelet counts also has given satisfactory results. The operative mortality ranges from 6 to 8 per cent in the chronic cases as compared with 70 to 80 per cent in the acute cases. The rapid course of the disease makes it imperative to choose the proper period of the disease for surgical intervention. The indications for surgical intervention depend on the duration and severity of the disease. The complications following splenectomy done in acute cases do not appear following operation done during the chronic stage.

[COMPILERS' NOTE.—Our knowledge of the dyscrasias associated with splenomegaly is increasing. The value of splenectomy in some of these conditions remains problematic. Giffin²⁷ stated, however, that in two diseases, namely, hemolytic jaundice and purpura hemorrhagica,

26. Anschütz, W.: Ueber Milzexstirpation bei Thrombopenien mit besonderer Berücksichtigung der akuten Fälle, *Beitr. z. klin. Chir.* **142**:1, 1928.

27. Giffin, H. Z.: Splenectomy, In: *Collected Papers of the Mayo Clinic*, Philadelphia, W. B. Saunders Company, 1927, vol. 19, pp. 637-644.

the results following splenectomy are so uniformly good that the indication for the operation depends almost entirely on a satisfactory diagnosis being made. W. J. Mayo²⁸ said that it is in the three blood dyscrasias, splenic anemia, hemolytic icterus and purpura hemorrhagica, that splenectomy is seen at its best.]

STOMACH

Duodenal and Gastric Ulcers.—Deaver²⁹ was of the opinion that operation is preferable to medical management in chronic ulcers of the duodenum and stomach. In bleeding duodenal ulcers, excision by knife or cautery, if possible, is advisable, and this should be followed with gastroduodenostomy or gastro-enterostomy. Deaver does not advocate subtotal gastrectomy for duodenal ulcer, unless, in the case of a bleeding ulcer, it is not possible to remove all of the periulcerous exudate with the ulcer. Subtotal gastrectomy, however, is indicated in gastric ulcer with very few exceptions. He favors the Billroth II type of resection.

Lewishon³⁰ said that duodenal ulcers and gastric ulcers are grouped collectively under the term gastroduodenal ulcers by many European surgeons because they believe that the etiologic factors are the same in both lesions. There are three surgical methods of treating ulcers: (1) local excision with or without gastro-enterostomy, a procedure which is often impossible because of an immobile duodenum or because of the site of the ulcer; (2) sleeve resection, which may or may not result in an hour-glass contraction of the stomach, and (3) partial or subtotal gastrectomy.

Lewishon stated that subtotal gastrectomy for both gastric and duodenal ulcer is the operation of choice because in this procedure the ulcers are entirely removed; the acid-bearing portion of the stomach is removed and the gastric acidity is greatly reduced thereby. He said that the mortality is low and the number of recurrences is less than after gastro-enterostomy.

[COMPILERS' NOTE.—Duodenal ulcer and gastric ulcer are separate and distinct lesions. Their etiology is not known. Duodenal ulcer occurs ten times as frequently as gastric ulcer. A duodenal ulcer almost never becomes malignant. Gastric ulcer may be malignant from the start, or it may become malignant. Duodenal ulcer is a combined medical and surgical problem. Every gastric ulcer is a surgical problem.

28. Mayo, W. J.: The Enlarged Spleen, In: Collected Papers of the Mayo Clinic, Philadelphia, W. B. Saunders Company, 1927, vol. 19, pp. 624-631.

30. Lewishon, Richard: Gastroduodenal Ulcers: Partial Gastrectomy Versus Gastro-Enterostomy in Their Surgical Treatment, J. A. M. A. 89:1649 (Nov. 12) 1927.

Whenever possible in duodenal ulcer, we excise the lesion, take out a section of the pyloric sphincter muscle and close it as in gastro-duodenostomy. All gastric ulcers should be excised. This is done either by local excision combined with gastro-enterostomy or by partial gastric resection. Occasionally a gastric ulcer is so situated that it cannot be excised.]

Hemorrhage from the Stomach and Duodenum.—Balfour³¹ said that massive hemorrhage in patients with duodenal and gastric ulcer rarely is fatal, and that repeated hemorrhages may or may not result in severe secondary anemia. Surgical treatment in acute, massive gastric hemorrhage is to be avoided because the mortality rate is higher than when patients are treated by medical means. Duodenal ulcer is the most common cause of hemorrhage from the stomach and duodenum. Of 1,072 patients operated on for duodenal ulcer, there was a history of gross hemorrhage in 184 (18 per cent). Blood was passed by bowel alone in 25 per cent, and was vomited alone in 27 per cent. Forty-eight per cent of patients gave a history of having vomited blood and passed it by rectum. Half of the patients had one hemorrhage only; the other half could recall two or more hemorrhages. The intervals between hemorrhages varied from one month to eighteen years. Patients with duodenitis may or may not give a history of hemorrhage. The causes of gastric and duodenal hemorrhage are not clear. Sometimes erosion of the gastroduodenal or superior pancreaticoduodenal artery seems to be the cause. In some cases gross defect cannot be found in the mucous membrane to account for the hemorrhage.

Mann, as a result of his experience in experimentally produced ulcers in dogs, was of the opinion that the hemorrhage may come from vascular buds in the granulation tissue which forms in the base of a healing ulcer or that actual mucous erosions are responsible. Such erosions often heal with great rapidity and do not leave a scar.

The treatment for duodenal ulcer associated with hemorrhage is surgical. The object is to relieve the patient of the symptoms of ulcer and to protect him against recurrence of the hemorrhage. Direct excision of the lesion, or cauterization, are the best methods of attack. Indirect operative procedures are of less value. Balfour stated that only 22 per cent of duodenal ulcers can be excised.

Balfour found that gastric ulcer is complicated by gross hemorrhage in 20 per cent of cases. Fatal hemorrhage from a gastric ulcer is rare. In bleeding gastric ulcers hematemesis occurred alone in 28 per cent, melena alone in 10 per cent, and both hematemesis and melena occurred in the same person in 62 per cent of cases. Gastric ulcers were surgi-

31. Balfour, D. C.: Management of Lesions of the Stomach and Duodenum Complicated by Hemorrhage, J. A. M. A. 89:1656 (Nov. 12) 1927.

cally accessible in 87 per cent of cases. In gastric carcinoma, gross hemorrhage occurred in only 7.5 per cent of cases. Microscopic hemorrhage, on the other hand, is common in cases of carcinoma.

Delore and de Girardier³² stated that the question of whether hemorrhage from gastric or duodenal ulcers belongs to the domain of the clinician or the surgeon is still a subject of debate. Cases of hemorrhage cannot be referred to as mild, moderate and severe, because alarming symptoms may arise in cases of profuse hemorrhage and yet the patient may make a rapid recovery provided hemorrhage does not recur. The difficulty and danger lie in recurrence of the bleeding. The source of the hemorrhage varies. It may come from the highly inflamed mucosa surrounding the ulcer or from erosions of smaller or larger vessels; the latter occurrence is more frequent than is generally thought. The prognosis in each case is therefore doubtful. The medical treatment consists of rest, lavage with hot water, injections of serum and blood transfusions. Why one patient may recover and another may not, under medical treatment, cannot be determined. Surgical treatment, therefore, is justified, although its seriousness is not to be minimized. If the patient comes under observation during the first hemorrhage, operation should be postponed until he has recovered from the immediate shock. If a patient comes under observation after repeated hemorrhage, the indication for operative procedure is further supported. Delore and de Girardier stated that the ideal procedure at operation is resection. Gastro-enterostomy should be limited to those cases with stenosis of the duodenum.

[COMPILERS' NOTE.—In both preoperative and postoperative bleeding from the stomach or duodenum, it is well to wait as long as possible before resorting to transfusion of blood. The sudden rise in blood pressure following transfusion frequently starts a fresh hemorrhage and may do more harm than good.]

Gastrojejunal Ulcers.—Wright³³ believed that gastrojejunal ulcers may occur after partial gastrectomy, rarely after pyloroplasty, and most often after gastro-enterostomy. He expressed the opinion that the cause of the primary ulcer is probably, also, the cause of the secondary ulcer. Gastric acidity is an important etiologic factor because the secondary ulcers form at the stoma where the acids have not yet been neutralized and because gastrojejunal ulceration occurs most commonly after gastro-enterostomy for duodenal ulcer which is accompanied by high acidity. Gastrojejunal ulcers occur less frequently following gastro-enterostomy in patients in whom the acids have been markedly

32. Delore, X., and de Girardier, J.: *Au sujet du traitement chirurgical des hémorragies gastro-duodénales d'origine ulcéreuse*, Presse méd. **36**:1092, 1928.

33. Wright, G.: *Gastro-Jejunal Ulceration*, Canad. J. M. & S. **63**:8, 1928

reduced by operation. The type of suture material used, and the use of clamps, are not of much significance in the etiology. Infection is a more significant factor, and Wright never does gastro-enterostomy in the presence of perforation, preferring merely to close the opening.

Gastrojejunal ulceration usually follows gastro-enterostomy, especially the Roux type of operation or gastro-enterostomy with entero-enterostomy. Fifty per cent of the secondary ulcerations are on the line of the anastomosis and encroach on both the stomach and the jejunum. Gastrocolic fistula, when present, usually follows posterior gastro-enterostomy. When secondary ulceration occurs after anterior gastro-enterostomy, it frequently presents itself in the anterior abdominal wall. Tenderness over the left rectus muscle, opposite or a little below the umbilicus, is an important physical sign. Roentgenographic examination may show irregularity of the stoma, and the stoma always is narrowed.

The methods of treatment have varied. The ulcer may be excised locally; the anastomosis may be excised together with the ulcer and a new anastomosis may be made; the anastomosis may be excised and the normal gastro-intestinal channel may be restored; finally partial gastrectomy may be done, which according to Wright is the operation of choice. When a jejunocolic or gastrocolic fistula is present, the organs must be separated and the opening in the colon must be closed, after which the other conditions are attended to. It is best to do a secondary operation before a colonic fistula develops.

Lewishon³⁰ reported 92 operations of gastro-enterostomy for ulcer of the duodenum at Mount Sinai Hospital in New York from 1915 to 1920. Of these, 47 per cent resulted in cure, 19 per cent of the patients still had slight complaints and 34 per cent developed gastrojejunal ulcers. Since November, 1922, all patients with duodenal and gastric ulcers at Mount Sinai Hospital have been treated by subtotal gastrectomy. Lewishon recommended this procedure without hesitation in all cases of gastric and duodenal ulcers.

[COMPILERS' NOTE.—The percentage of jejunal ulcers following gastro-enterostomy for duodenal ulcer is difficult to determine, but in our experience the frequency is about 3 per cent. Gastrojejunal ulceration occasionally follows partial gastrectomy for duodenal ulcer. We believe that most duodenal ulcers can be handled better by some less radical procedure than partial gastric resection. That absolutely sound principles have not been arrived at in the treatment for duodenal ulcer is shown by the different methods used in various clinics and is perhaps best exemplified by what has happened at Bier's clinic in Berlin. There change has been made from doing simple gastro-enterostomy in cases of duodenal ulcer to the radical method of resection, then back again to doing gastro-enterostomy, and at the present time a stand midway

between the two is taken. We prefer, if possible, to excise duodenal ulcers, but gastro-enterostomy has given excellent results in many cases, especially if there is pyloric obstruction.]

Starlinger³⁴ has shown by experiments on dogs that the mucosa of the descending portion of the duodenum has increased resistance against formation of ulcer. He does not believe that it is the neutralizing effect of bile and pancreatic secretion alone which prevents formation of ulcer in dogs after end-to-side gastroduodenostomy. In man, this operation may be considered as especially likely to prevent the formation of secondary ulcers. In this procedure, however, there is the possibility of obstruction by pressure from the superior mesenteric artery. Starlinger has tried to prevent this by a modification in technic. He mobilizes the duodenum from both sides, cuts the duodenum and reunites it by end-to-end anastomosis in front of the mesenteric artery, bringing the anastomosis through a new opening in the mesocolon near the middle colic artery. He stated that only time will determine whether this method of gastroduodenostomy modeled after the Billroth I method will be of value in the surgical management of cases of gastric and duodenal ulcer.

Wilkie² has recently been doing gastroduodenostomy after the manner of von Eiselsberg in cases of duodenal ulcer. He joins the anterior portion of the stomach near the pylorus to the second portion of the duodenum about opposite the ampulla of Vater. In this procedure, it is necessary to mobilize the second and third portions of the duodenum, which readily can be done by incising the peritoneum along the outer or convex border of the duodenum. Wilkie believed that this procedure offers all the advantages of gastrojejunostomy and practically eliminates the danger of the occurrence of a secondary or stomal ulcer, because the acid content of the stomach is emptied into the intestine near the same point that the alkaline secretions, bile and pancreatic juice enter the bowel.

Gastritis.—Konjetzny³⁵ was of the opinion that recent anatomic and clinical investigations have awakened new interest in the treatment for gastritis. He gave the following suggestions for detecting gastritis in its acute and chronic form at the time of operation. In acute gastritis, there is marked reddening of the serosa and more or less edema of the gastric wall which makes it seem plastic. The regional lymph

34. Starlinger, G.: *Versuche zur Säureresistenz und Geschwürsbereitschaft des infrapapillären Duodenums, sowie zum Ausbau der terminolateralen Gastroduodenostomie im Rahmen der ersten Methode Billroths*, Arch. f. klin. Chir. **149**: 593, 1928.

35. Konjetzny, G. E.: *Gibt es eine Anzeige zur chirurgischen Behandlung der Gastritis?* Arch. f. klin. Chir. **151**:370, 1928.

nodes are freshly enlarged and soft. There is slight edema of the gastric attachments of the mesogastrium and gastrocolic ligament.

Chronic gastritis, when associated with subacute inflammatory reactions, causes reddening of the serosa overlying the pyloric antrum. This corresponds to Schoemaker's "red stomach." There is more or less thickening of the gastric wall; the thickness increases from the antrum to the pylorus. This increased thickness of the gastric wall, as the pylorus is approached, is almost pathognomonic of chronic gastritis. There may be tumor-like thickening of the pylorus, often with pyloric obstruction which Konjetzny termed "stenosing gastritis." The thickening of the gastric wall may be nodular, a type which is called hyperplastic gastritis. Perigastritis usually is present on the posterior wall. There is chronic inflammatory enlargement of the lymph nodes along the greater and lesser curvature, most marked in the region of the antrum. Clinically, these two main types are often combined; the most marked evidence of inflammatory reaction is in the pyloric region.

The problem of gastritis is of clinical significance: first, because of the frequent recurrence of attacks of acute gastritis in cases with chronic inflammatory changes in the gastric mucosa; second, because epithelial proliferation in chronic gastritis generally is conceded to have precancerous proclivities.

Konjetzny discussed the indications for the surgical treatment in acute gastritis and presented three cases in which the clinical picture resembled that of perforated ulcer with peritoneal involvement. Severe hemorrhages may occur in gastric erosions which may develop in acute gastritis, and operation, in these instances, must depend on accurate determination of the source of the bleeding. A bleeding ulcer demands operation, but generalized bleeding from acute gastritis may tax the ingenuity of the surgeon as to whether surgical or medical management would give the best results. By gastrotomy, definite evidence may be gained of the source and nature of the bleeding. Jejunostomy has given good results when performed in cases of diffuse gastric hemorrhage. Konjetzny believed that medical treatment should be given in cases of simple acute ulcerative gastritis and that they should be considered of a surgical nature only if they fail to respond to medical management. Only those cases in which the gastritis is confined to the antrum pylori are amenable to surgical treatment. Generalized gastritis is not a surgical condition.

Pyloric stenosis and pylorospasm frequently are found associated with chronic gastritis. In most of the specimens of stomachs resected for chronic gastritis, thickening of the pyloric muscle is found. In hyperplastic chronic gastritis, or polypoid gastritis, there may be evidence of carcinomatous degeneration. Such precarcinomatous and carcinomatous areas may be present also in atrophic gastritis. The

polypoid form of gastritis usually can be diagnosed with the aid of the roentgen rays, but the diagnosis of atrophic gastritis can be made only by exclusion. In certain cases, gastroscopic examination has given the necessary evidence.

Konjetzny said that pyloroplasty has not been found satisfactory in the surgical management of acute or chronic gastritis, but has proved of value in cases of pylorospasm without definite evidence of gastritis. Polypoid gastritis presents a surgical indication for resection. The surgical indications in cases of simple atrophic gastritis are indefinite. Several cases in which resection has been performed showed beginning carcinomatous changes, and surgical intervention in this group remains an open question. Gastro-enterostomy has proved definitely harmful in cases of simple chronic gastritis.

[COMPILERS' NOTE.—Inflammatory lesions have a definite place in diseases of the stomach and duodenum. Duodenitis, either alone or in association with duodenal ulcer, is relatively common. Gastritis also occasionally occurs alone but usually is found in association with gastric or duodenal ulcer. We also have operated in several cases of supposed gastrojejunal ulceration and have found only well marked jejunitis and gastritis without true ulcer.]

Pylorospasm in Adults.—C. H. Mayo³⁶ said that it is probable that neither duodenal nor gastric ulcer occurs without accompanying pyloric spasm. Disease of the appendix and gallbladder tends to produce pyloric spasm. The pylorus and duodenum get their nerve supply from a large branch of the vagus that goes directly from the region of the cardia to the liver. For the last two years, in cases in which trouble in the stomach is due to reflex spasm of the pylorus, C. H. Mayo has divided the muscle of the pyloric ring at the upper border; in some cases also he has cut away the superior attachment of the first 2.5 cm. of the duodenum and the last 2.5 cm. of the pylorus in the hope of separating the branches of the vagus at this point. Because lesions at the angle of the stomach produce marked pylorospasm, C. H. Mayo recently has been dividing the tissues above the angle, cutting into the wall of the stomach so as to be sure of dividing the branches of the vagi. This slight additional procedure apparently has been of some benefit, but many further observations will have to be made before definite conclusions can be reached.

Hypertrophic Pyloric Stenosis in Infants.—Kirschner³⁷ reported 21 consecutive operations without mortality for pylorospasm in infants.

36. Mayo, C. H.: Division of the Vagi for Pylorospasm, *Ann. Surg.* **88**:669, 1928.

37. Kirschner: Die operative Behandlung des Pylorospasmus der Säuglinge, *Arch. f. klin. Chir.* **152**:509, 1928.

He used an incision in the median line and divided the pyloric muscle longitudinally with a knife. He emphasized that the muscle must be completely divided. The incision should extend a little onto the stomach and onto the duodenum. Kirschner considered the operation indicated when the infant has failed to improve after from five to eight days on medical management.

Kühl,³⁸ in discussing Kirschner's paper, pointed out that it is incorrect to give the impression that there is no risk in operating on infants for pylorospasm. He estimated the mortality rate at about 16 per cent.

Cardiospasm.—Keller,³⁹ in a case in which nonoperative dilatation of the cardia was unsuccessful, made an anastomosis between the fundus of the stomach and the lower end of the esophagus. The patient was cured. The operation is not offered as a substitute for nonoperative treatment of cardiospasm when done by an expert, but in view of the fact that the mortality following nonoperative dilatation in general hands is high, this operation, according to Keller, presents a method whereby the general surgeon may handle such cases.

[COMPILERS' NOTE.—In most cases, cardiac spasm can be cured by dilatation through the esophagus. A hydrostatic dilator is used and is guided into position by means of a silk thread which previously has been swallowed. Often a single dilatation is sufficient, but sometimes the procedure has to be repeated. We⁴⁰ recently were forced to operate on a patient in whom the hydrostatic dilator could not be introduced. In this case the stomach was opened and the cardiac opening was dilated manually from below.]

Gastric Ulcer and Carcinoma.—Scott⁴¹ was of the opinion that carcinoma does not develop from chronic gastric ulcer as often as is generally believed. He thought that many of the gastric ulcers in which there is coexisting carcinoma were primarily carcinomatous. Scott stated that there is no clinical method of distinguishing between a chronic gastric ulcer and early carcinoma with ulceration. All gastric ulcers, therefore, should be treated as though they were carcinomatous.

Walton⁴² was able to establish a definite relationship between gastric ulcer and carcinoma in 25 cases from a series of 228 cases of carcinoma of the stomach in which surgical treatment was employed.

42. Walton, A. J.: Carcinoma of the Stomach, Lancet **2**:438, 1928.

[COMPILERS' NOTE.—Opinions differ as to the number of benign gastric ulcers which may become malignant. Moynihan⁴³ gave a figure as high as 21.8 per cent. Most German surgeons believe the association of malignant lesions and gastric ulcer an incidental occurrence rather than that one is secondary to the other. The significant point is that a certain number of gastric ulcers are malignant, whether they were malignant from inception or not, and gastric ulcer is, therefore, a surgical lesion.]

Carcinoma of the Stomach.—Balfour⁴⁴ advocated partial gastric resection in two stages for carcinoma of the pyloric end of the stomach with lymphatic involvement, with posterior fixation and with marked inflammatory reaction of the surrounding tissues. First, an anterior or posterior Polya type of operation, with or without entero-anastomosis, is done, and the pyloric end of the stomach is closed. In from ten to twelve days, when the condition of the patient is improved and the inflammation has had a chance to subside, the pyloric end of the stomach can be removed.

Walton⁴² reviewed the pessimism in the public mind regarding the fatal issue in carcinoma. This is especially true of carcinoma of the stomach because the early diagnosis is associated with much difficulty and the late prognosis is unsatisfactory. He presented a series of 229 cases of carcinoma of the stomach in which operations were done and 1,086 cases of simple chronic ulcers in which the patients, likewise, were subjected to operation during the same period, from 1913 to 1928. In this series there was one carcinoma of the stomach for every six gastric operations. Walton presented a chart showing that the cases with ulcer during this period have increased threefold, whereas the number of carcinomas has remained constant year by year. Duodenal ulcers are included in the chart and form the largest proportion of this series. Ulcers of the lesser curvature of the stomach also have increased threefold since 1913. To explain the relative increase of benign ulcer over carcinoma, Walton suggested that many patients have been saved from carcinoma by having ulcers treated surgically during the benign stage.

Since recurrences following operations for carcinoma of the stomach are found most frequently in the liver and deep lymph nodes, Walton was of the opinion that improvement in late results does not lie in more extensive operations. The fact that only about a third of the total number of patients with carcinoma are operated on when first seen led Walton to state that any persistent dyspepsia, occurring after the

44. Balfour, D. C.: A Method of Carrying Out Two-Stage Operations for Carcinoma of the Stomach, *J. A. M. A.* 90:1936 (June 16) 1928.

age of 40 years in a patient with a clear history, is to be regarded as due to carcinoma until the disease can be definitely eliminated.

Benign Gastric Neoplasms.—Balfour²¹ said that only 1 per cent of gastric neoplasms are benign. He classified 50 benign neoplasms of the stomach as follows: fibro-adenomatous polyps, 14; adenomas, 4; fibromas, myomas, fibromyomas, adenomyomas and myxofibromas, 23; hemangiomas, 4; polyposis, 4; hypertrophied mucosa, 2; papilloma, 1; dermoid cysts, 3, and hypertrophied pyloric muscle, 3.

Balfour stated that if a lesion can be shown to be present in the stomach, even in the absence of hemorrhage or marked symptoms, the treatment is surgical because it has been shown that 3 of 4 intragastric lesions are malignant (McVicar).

APPENDIX

Acute Appendicitis.—Eliason and Ferguson⁴⁵ have called attention to the fact that appendicitis has been little discussed since 1915. They found that the mortality from acute appendicitis has risen in the last twelve years. Statistics show that death occurs most frequently in those cases in which the diagnosis is delayed until the disease is not any longer confined to the appendix.

Eliason and Ferguson studied 675 cases which by laboratory reports and examination of gross specimens were proved to be cases of acute appendicitis. As soon as the diagnosis was made, operation was performed. Every patient was operated on in whom rigidity overshadowed distention, providing the vascular system was still competent. Low blood pressure associated with high temperature and cold extremities was a contraindication to operation. In cases of delayed operations, the incision was made under local anesthesia and a drain was placed in the pelvis; the appendix was not removed unless it presented in the wound. Drainage was necessary in at least one of every four cases, and was most often necessary in those patients who were less than 10 or more than 40 years of age.

From a diagnostic point of view, too much stress has been placed on tenderness over McBurney's point. Of 468 patients, only 44.7 per cent had tenderness in this region. Thirty-one per cent had rectal pain and tenderness. In 16.9 per cent of patients in whom the appendix was in the pelvis, pain was felt in the epigastrium. Rigidity was absent in 34.2 per cent of the cases in which the appendix lay to the left of the cecum and over the brim of the pelvis, and was most marked in cases in which the inflammation extended by contiguity to the abdominal wall.

45. Eliason, E. L., and Ferguson, L. K.: Mortality Factors in Acute Appendicitis, *Ann. Surg.* 88:65, 1928.

Nausea and vomiting, fever and leukocytosis are not constant reliable signs. In from 60 to 70 per cent of cases, one or more symptoms were atypical; in 18.6 per cent the leukocyte count was less than 10,000.

The mortality rate in the entire series was 5.5 per cent. In the cases in which drainage was not instituted, the mortality was 1.07 per cent. Approximately 50 per cent of the patients did not reach the surgeon until the third day, and 34 per cent did not reach the surgeon until the fourth day. The most frequent complications were peritonitis and intestinal obstruction; peritonitis was the greatest factor in the mortality.

[COMPILERS' NOTE.—The problem of acute appendicitis remains one of early diagnosis and operation. This depends on the confidence of the laity in the physician and the acumen of the physician, and is not likely to undergo any immediate radical change.]

Martens⁴⁶ stated that the mortality in patients with appendicitis associated with chills is double that of similar cases without chills. All patients with appendicitis who have chills should be operated on immediately. If twenty-four hours intervened between the first chill and the time the patient is operated on, it is advisable to ligate the ileocolic vein, especially if there is inflammatory infiltration of the mesocolon. It is best also to remove the entire meso-appendix. If pus is encountered in the meso-appendix, ligation of the ileocolic vein also is indicated. If chills develop after appendectomy for acute appendicitis, or if other symptoms of pyemia develop, Martens advised that the abdomen be reopened and the ileocolic vein ligated. If chills continue to recur after an operation for acute appendicitis, careful study of the blood picture, roentgenographic examination and punctures of the liver may reveal the presence of hepatic abscess. The timely drainage of such an abscess may prevent an otherwise fatal termination.

Deaver⁴⁷ believed that the appendix deserves first place as a focus of infection, not excepting the teeth, tonsils and sinuses. He stated that duodenal ulcer, gastric ulcer and cholecystitis, and abscesses of the liver are frequently due primarily to an infected appendix. Deaver was of the opinion that when a diagnosis of appendicitis has been made in the absence of general peritonitis, appendectomy should be done at once, because he believed that expectant treatment has resulted in many complications and deaths. He placed more stress on a high proportion of polymorphonuclear leukocytes in the differentiated blood smear than on a leukocyte count.

47. Deaver, J. B.: Appendicitis, J. A. M. A. 90:1679 (May 26) 1928.

Drainage for Appendicitis.—Weeden⁴⁸ advised the use of the Gibson-Mikulicz drain in operations for acute appendicitis. The drain consists of a square of rubber dam folded two or three times in the form of a cornucopia. The apex of this cornucopia, which forms the lowest point of the dam, is snipped off and 3.75 cm. above this, the edges of the cornucopia are cut out making a perforation of 1.25 cm. With the finger in the apex, the tampon is filled with strips of packing. When the drain is removed on the third or fourth day, a cavity about 10 cm. in diameter remains. This method affords a large amount of drainage.

Weeden reported a series of 1,588 appendectomies for acute appendicitis. In 728 (45.84 per cent), closure was without a drain and in 860 (54.16 per cent) drainage was instituted. The mortality rate in the cases in which drainage was instituted was 4.9 per cent, and in the cases in which drainage was omitted, 0.55 per cent. In Weeden's opinion, the drain is most valuable in those cases in which there is spreading peritonitis. Other advantages are that there is immediate lessening of toxemia, as shown by lowered temperature and pulse rate; the drain is easily removed and the wound is left open, therefore there is no secondary infiltration or infection of the abdominal wall; there is practically never any pocketing or formation of secondary abscesses and fecal fistulas develop in only a small number of cases (1.2 per cent); the adhesions produced, while firm enough to form a cavity for abscess, nevertheless do not give trouble and apparently disappear later. The disadvantages of the drain are that it increases the period of hospitalization; the average time, being 23.4 days as against from 17.1 to 18.6 days with other types of drains; hernia occurs in from 11.4 to 14 per cent of cases, and there is a possibility of evisceration, but this rarely occurs. Weeden believed that the advantages of the drain far outweigh its few disadvantages.

Traumatic Appendicitis.—McGeary⁴⁹ was of the opinion that the question of traumatism as a possible etiologic factor in appendicitis is of interest to the surgeon because of its medicolegal aspects. The dependent position of the appendix, its rather poor supply of blood and its bacteria-filled lumen are factors which must be considered in estimating injury to the appendix. McGeary presented data from five cases in which appendiceal symptoms and pathologic lesions in the appendix were present after traumatism of various forms. He said that if appendicitis is accepted to be the result of an accident or of trauma,

48. Weeden, W. M.: The Gibson-Mikulicz Drain in Acute Appendicitis: With Report of 1,588 Cases, *Ann. Surg.* **88**:76, 1928.

49. McGeary, W. C.: Traumatic Appendicitis, *Internat. J. Med. & Surg.* **41**:449, 1928.

there should be good corroborative evidence that there has been a more or less definite continuous train of symptoms from the date of the accident to the time of the appendiceal attack.

Appendicitis in Children.—Walton⁵⁰ said that chronic appendicitis in children under 14 years of age is rare and often is confused with a condition that really is acute. This is due to the fact that early symptoms often are overlooked or discounted in young children. A diagnosis of chronic appendicitis in adults usually means visceroptosis and operation should not be done. However, in children the diagnosis of chronic appendicitis often in reality means an acute condition, and immediate operation is indicated.

Chronic Appendicitis.—Smith⁵¹ expressed the opinion that in the disease known as chronic appendicitis the appendix may be implicated but often is not, and its removal frequently fails to relieve symptoms. He believed that in many cases the symptoms are due to kinking and obstruction of a mobile cecum by peritoneal bands. In cases in which the cecum is dilated and thin-walled, instead of trying to plicate or suspend it, he relieves the constriction by cutting the offending peritoneal band and covers the raw surface with a free omental graft. The cecum immediately resumes its normal tone, color, thickness and peristaltic activity. In a series of 420 cases diagnosed as cases of chronic appendicitis, Smith had only 202 cases in which he believed symptoms would be relieved by appendectomy alone. In the remaining 218 cases, it was necessary to deal with other pathologic conditions encountered; in 186 of these there were definite pericolic membranes which crippled cecal peristalsis and caused cecal block.

[COMPILERS' NOTE.—The diagnosis of chronic appendicitis probably is too frequently made. A definite history of previous acute attacks is significant in making a diagnosis. In cases of indefinite abdominal symptoms all other possible causes for distress must be investigated.]

Various Positions of the Appendix.—Wakeley and Gladstone⁵² analyzed 5,000 cases in which the position of the appendix was noted at operation, at necropsy and in the dissecting room. The postcecal and retrocolic positions of the appendix were those most commonly observed; the appendix was in one or the other of these positions in 64.3 per cent of cases. The pelvic or descending position occurred in 32.1 per cent of cases. Other positions of the appendix were less commonly seen.

COLON AND RECTUM

Carcinoma.—Rankin⁵³ emphasized the significance of adequate preparation before resection in carcinoma of the colon and rectum. This consists primarily of adequate cleansing of the gastro-intestinal tract, supportive and dietary measures, and the institution of drainage by colostomy, preliminary to subsequent resection. Rankin performed twenty-six anterior resections of the rectosigmoid and of the upper part of the rectum with only one death.

Rankin⁵⁴ reported the use of spinal anesthesia in carcinoma of the colon, with good results. Its advantages are complete relaxation during operation and the absence of postoperative pulmonary complications. Statistical studies of large groups of cases of carcinoma of the colon and rectum indicate that in a high percentage of cases there is freedom from recurrence for from three to five years or more.

Rankin and Broders⁵⁵ made a study of the factors which influence the prognosis in carcinoma of the rectum and they found that the grade of malignancy determined according to Broders' classification is of greatest significance. They found that the total of good results following operations for carcinoma of the rectum decreased in inverse proportion to the grade of malignancy, whereas the total of poor results increased in proportion to it.

Stoger⁵⁶ stated that most German surgeons favor resection in carcinoma of the rectum, with conservation of the sphincter if possible. Of 303 cases, Stoger was able to resect the growth and to save the sphincter in 76. The mortality in this group was 15.8 per cent; 44.8 per cent remained well for a period of five years or more; 8 patients were well more than ten years and 4 more than twenty years following operation. All had normal function of the rectal sphincter.

Kirschner⁵⁷ stated that the ideal surgical method for treating carcinoma of the rectum has not been determined. He believed that every case of carcinoma of the rectum should be approached by the abdominal sacral route. By opening the abdomen, metastasis, if present,

53. Rankin, F. W.: The Technique of Anterior Resection of the Rectosigmoid, *Surg. Gynec. Obst.* **46**:537, 1928.

54. Rankin, F. W.: Surgical Procedures in Carcinoma of the Large Bowel, *J. Michigan M. Soc.* **27**:465, 1928.

57. Kirschner, M.: Alte und neue Vorschläge zur Ausrottung des Mastdarmkrebses, *Der Chir.* **1**:1, 1928.

can be found and dissection can be carried out under direct vision with less danger of hemorrhage and infection; also, the mortality is lower in this method. Although Kirschner formerly recommended removal of the sphincter in all cases, he now recommends saving it whenever possible. The results in these cases are satisfactory. He believes an abdominal anus is always preferable to a sacral anus.

Küttner⁵⁸ reviewed a series of 1,301 cases of carcinoma of the rectum. Sixty-three per cent occurred in men and 36.7 per cent in women. The growth was close to the anus in 0.3 per cent. The prognosis in this group was poor, as early metastasis to the inguinal lymph nodes takes place. Seven and three tenths and 11.5 per cent of tumors occurred, respectively, in the pars perinealis and in the ampulla of the rectum; in these the prognosis was good. Sixty and seven-tenths per cent occurred in the ampulla proper; in this group, the prognosis was not so favorable, as the condition usually was discovered late. Eleven per cent occurred near the flexure; most of these cases are inoperable. Küttner recommended saving the sphincter whenever possible. He makes a sacral anus, as a rule, and uses the combined abdominal sacral operation only occasionally; he stated that it must first be shown that the mortality in this method is no greater and that the results are better. He reported 480 radical operations with 108 deaths, a mortality of 22.5 per cent.

In a group of 150 cases in which operation was done in the last seven years, the mortality was 16.4 per cent. Thirteen patients were operated on by the abdominal sacral route, and in this series there were 7 amputations of the rectum, with 2 deaths, a mortality of 29.5 per cent, and 6 resections with 4 deaths, a mortality of 66.6 per cent. The results following radical operation on the patients who survived operation were: patients living three years or longer, 46.5 per cent; more than five years, 32 per cent; more than eight years, 24.1 per cent, and more than ten years, 19 per cent. Of those patients who underwent palliative colostomy, 70 per cent died within the first year, 6 per cent lived three years and 2 per cent lived five years.

[COMPILERS' NOTE.—Surgical procedures in carcinoma of the colon are accompanied by a relatively high risk because of the presence of infection and because of the relatively poor supply of blood to the colon. Delayed healing following operation is due not to an actual paucity of blood supply to the colon, but to a lack of adequate anastomosing vessels. Preoperative preparation of patients is important. In cleaning out the gastro-intestinal tract, however, care must

58. Küttner, Hermann: *Der Mastdarmkrebs und seine chirurgische Behandlung*, Med. Klin. 25:4, 1929.

be taken not to lower the patient's resistance by too prolonged rest in bed, by catharsis or by insufficient diet.]

Blood Supply of the Colon.—Fischer⁵⁹ described two types of small arteries that are given off from the vessel that runs longitudinally in the mesentery, close to the attachment of the bowel. The smaller vessels supply that portion of the bowel which is near its mesenteric attachment. The larger vessels encircle the bowel and supply blood to the portion opposite the mesenteric attachment. These larger vessels pass through the bases of the appendices epiploicae. When the colon is fully distended, the vessels lie flush with the surface of the bowel, but when the intestine is collapsed they form a loop extending some little distance into the appendixes. In tying off the appendixes, these vessels are likely to be injured, thus interfering with the blood supply on the contramesial side of the bowel. Fischer recommended end-to-end anastomosis of the colon, but said that the bowel should be cut through diagonally and that care should be taken not to injure the vessels already described.

Colostomy.—Demel⁶⁰ devised an artificial abdominal anus which allows the patient to control bowel movement directly. The method consists in bringing out a portion of the bowel and surrounding it with a cylinder of skin. By a special mechanical device the patient can keep this part of the bowel clamped off and thus prevent the passage of content of the bowel through the distally placed opening. Demel performed the operation on six patients with good results. Closure of the bowel is well tolerated up to twelve hours.

[COMPILERS' NOTE.—Many methods have been devised for making a colostomy which will enable the patient to control the movements of the bowel. In our experience, complicated operations are unnecessary, and properly done colostomy, with the bowel brought out through a muscle-splitting incision on the left side, gives the best results. Lavage once daily, and simple dietary measures, are adequate to enable the patient to live in comfort and to attend to his work and pleasures in the normal manner.]

Diverticulitis of the Colon.—Monsarrat⁶¹ recommended conservative treatment rather than operation in acute diverticulitis of the colon, except in cases that have progressed to formation of abscess. Uncompli-

59. Fischer, A. W.: Inwieweit ist durch die Ablösung des Dickdarmfettheanges die Sicherheit der Dickdarmaht gefährdet, Arch. f. klin. Chir. **152**:638, 1928.

61. Monsarrat, K. W.: Remarks on Surgical Treatment of Diverticulitis, Brit. M. J. **2**:41, 1928.

cated cases of chronic diverticulitis, the more common form of the disease, also are best treated medically. If a patient with chronic diverticulitis is operated on, Monsarrat advised that the bowel be wrapped in omentum to prevent the formation of a fistula of the bladder.

[COMPILERS' NOTE.—A temporary colostomy by which the content of the bowel is shunted to the outside frequently is of value in diverticulitis, especially if the disease is fairly well localized. Often, after a few months, during which the lower segment of bowel is irrigated daily, the lesion has healed sufficiently to allow closure of the colostomy opening. Occasionally the lesion may be resected.]

Syphilis of the Colon.—Chastenet ⁶² reported two cases in which abscesses of the colon, adherent to the abdominal wall, one of which had a fecal fistula, apparently were of syphilitic origin.

Infectious Granuloma of the Colon.—Mock ⁶³ reported three cases of infectious granuloma of the intestines. Such tumors appear to be due to excess reparative processes following low-grade infection and necrosis. The growths often reach an appreciable size and are readily mistaken for malignant tumors.

Obstruction of the Colon.—Haggard ⁶⁴ stated that operations for acute intestinal obstruction are accompanied by a higher mortality than generally is supposed. The causes for this are the promiscuous use of purgatives, failure to recognize the conditions early and delay of operation. Haggard described enterostomy as a surgical method of treating intestinal obstruction. He called attention to the disturbances in chemistry of the blood and recommended the intravenous administration of solutions of dextrose and sodium chloride.

Rosenstein and Köhler ⁶⁵ studied the question of the control of intestinal peristalsis in animals and showed that the injection of nicotine into the celiac ganglion caused marked increase in peristalsis in normal animals as well as in those with peritonitis. Nicotine paralyzed the synapsis between the preganglionic and postganglionic fibers of the autonomic nervous system. By injecting nicotine directly into the celiac ganglion, the action controlled by the splanchnic nerves is diminished.

62. Chastenet, de Gery: Deux cas de sigmoïdite suppurée avec infiltration de la paroi abdominale chez des syphilitiques, Bull. et mém. Soc. Nat. de Chir. **54**: 834, 1928.

63. Mock, H. E.: Infective Granuloma of the Intestines, Internat. J. Med. & Surg. **41**:1, 1928.

64. Haggard, W. D.: Acute Intestinal Obstruction, J. A. M. A. **90**:1424 (May 15) 1928.

65. Rosenstein, Paul, and Köhler, Hans: Ueber die Beeinflussung der Darm-paralyse durch Nikotininjektion in das Ganglion coeliacum, Deutsche Ztschr. f. Chir. **210**:315, 1928.

As these nerves are the antagonists of the vagi or motor nerves of the bowel, the action controlled by the latter is thereby increased. This action occurs even though the vagus is injured by toxins. The vagus is not affected by injection of the celiac ganglion, as synapsis between its preganglionic and postganglionic fibers does not occur at this point.

Following a careful study of the action of nicotine in animals, its therapeutic value was tested in human beings. The dosage used was from 5 to 8 mg. of fresh nicotine in 50 cc. of sterile water. The action of the drug appeared to take place only locally; there was no general reaction as a result of absorption of the nicotine. The 26 patients in whom it was tried all had marked paralytic ileus, mostly as a result of peritonitis, and all other methods used to relieve the ileus had failed. Rosenstein and Köhler believed that the most significant factor in causing death in ileus is the absorption of toxic products from the content of the intestine; therefore, elimination of this content is indicated. The paralysis of the bowel was overcome in 17 of the 26 patients; 9 of them subsequently died. One patient had multiple abscesses in the abdominal cavity; 2 had bronchial pneumonia; 1 died of cardiac failure; 2 died of sepsis following abortion, and 3 died as a result of the progress of carcinoma. Eight of the patients recovered.

The technic of injection is that used by Kappis and Finsterer in their method of splanchnic anesthesia; the approach is from behind, with the patient preferably in a sitting position. The method never must be used in mechanical ileus, as to use it would only make the condition worse. Rosenstein and Köhler were of the opinion that this method is a step forward in the treatment for paralytic ileus.

Ochsner, Gage and Cutting⁶⁶ induced splanchnic anesthesia in dogs with 1 per cent solution of procaine hydrochloride and found that it relieved ileus and produced peristalsis. They recommend splanchnic anesthesia in paralytic and adynamic ileus, and in mechanical ileus after the obstruction has been relieved.

PERITONITIS

Salzer⁶⁷ traced the etiology of the majority of cases of diplococcal peritonitis to infection from the genitalia. The differential diagnosis from appendicitis is possible but is necessary only in young girls. In boys there is always preceding diplococcal appendicitis which requires

66. Ochsner, Alton; Gage, I. M., and Cutting, R. A.: Treatment of Ileus by Splanchnic Anesthesia: Preliminary Report of Experimental Study, *J. A. M. A.* 90:1847 (June 9) 1928.

67. Salzer, Hans: Die Diplokokkenperitonitis beim Kinder, *Deutsche Ztschr. f. Chir.* 208:226, 1928.

immediate operation. Girls should be treated expectantly until the presence of pus in the abdominal cavity becomes a possibility, then operation is indicated.

David⁶⁸ showed that *Bacillus coli* was taken directly into the blood stream, as well as into the lymphatics, from the peritoneum of a normal dog. He also showed that the presence of a plastic exudate produced by intraperitoneal injection of emulsion of turpentine greatly hindered or prevented the passage of bacteria into the lymph or blood stream, whereas the presence of hypertonic solution of dextrose in the peritoneal cavity increased the rate of absorption of bacteria.

David and Sparks⁶⁹ found in an experimental study that diphtheria toxin, when injected into the normal peritoneal cavity of a dog, passed directly into the blood stream, as well as into the lymphatics, in sufficient quantities to prove fatal to guinea-pigs. In the presence of well developed plastic peritonitis, there was practically no passage of diphtheria toxin into the chyle, and it passed into the blood stream in much smaller quantities than from the normal peritoneum. The presence of hypertonic solution of dextrose in the peritoneal cavity of dogs increased the rate of absorption of diphtheria toxin by the blood stream and by the lymphatics.

David and Sparks concluded that the formation of a plastic exudate was to be regarded as a favorable process in peritonitis. Although they do not wish to press the analogy between the peritoneum of the dog and of the human being, they believed from their experiments that in the early hours of peritonitis the absorption of toxins and bacteria from the circulation directly and by way of the lymphatics is the dominant factor of danger; later, absorption from the peritoneum becomes less significant and local conditions, such as paralytic ileus, gain the ascendancy.

Brown⁷⁰ found in experimental studies on cats and dogs, in which peritoneal absorption is much like that in man, that absorption by way of the thoracic duct from the peritoneal cavity is a slow and unimportant process. He also found that the omentum plays little, if any, part in actual lymphatic absorption from the peritoneal cavity. Brown concluded that lymphaticostomy cannot be recommended as a procedure offering any hope to patients suffering from acute peritonitis.

INTRA-ABDOMINAL HEMORRHAGE

Büttner⁷¹ attempted to answer the question of whether there is any worth while method of utilizing the blood found in the abdominal cavity in patients with severe intra-abdominal hemorrhage and turning it to a useful purpose. These patients suffer from the effects of diminished blood volume and accompanying deficiency in the oxygenating properties of blood; the first requirement is to supply these deficiencies. The most satisfactory method of accomplishing this is direct transfusion of properly grouped blood. Büttner suggested, as a matter of expediency, and because grouping would not be necessary, the possibility of reinfusing the functionally active free blood found in the abdominal cavity. There is also the danger of leaving large quantities of blood in the abdominal cavity for absorption by the peritoneum. The irritated peritoneum may be protected by evacuating any extravasated blood from the abdominal cavity.

THROMBOSIS AND EMBOLISM

Borchard⁷² stated that it is generally believed that thrombosis and embolism are on the increase but whether or not this is true is difficult to determine accurately. Thrombosis, embolism and infarcts must be considered together, and particular attention must be paid to the origin. Thrombosis of the saphenous vein often is incorrectly said to be the origin of a pulmonary embolus. Borchard saw a pulmonary infarct, and later thrombosis of the saphenous vein. The three factors in the causation of thrombosis are slowing of the blood stream, changes in the wall of the vessel and changes in the blood. He believed the condition of the blood to be the chief factor.

It is known that certain conditions predispose to thrombosis and embolism, namely, myoma, prostatic disease and carcinoma, especially carcinoma of the intestinal tract. On the other hand, operations on the thyroid gland are seldom followed by thrombosis and embolism. Infection increases the danger by two-thirds, especially if the infectious focus cannot be removed. Infections must also be considered which may have occurred several weeks previously, as, for example, influenza and angina. Slowing of the blood stream is significant in the first postoperative days, as the patient lies more quietly and breathes less deeply during this time. A great deal more statistical and experimental work must be done in order to clarify the ideas regarding the exact rôle of these causative factors. Treatment must be instituted largely on an empiric

72. Borchard, A.: Ueber Thrombose und Embolie, Beitr. z. klin. Chir. 144: 163, 1928.

basis. Particular attention must be paid to the patient's heart, lungs and general constitution. Age, the possible presence of endocrine disturbances and the coagulation time of the blood also must be considered.

Certain conclusions can be drawn as to the possibility of a patient developing thrombosis and embolism. Special attention should be paid to preoperative preparation. Following operation active and passive movements should be begun as early as possible. Peripheral emboli are not so much feared as formerly, as embolectomy is followed by good results. Embolus must not be considered by the surgeon as an act of fate; somewhere there must have been something which could have been foreseen or prevented.

Tempsky⁷³ made a statistical study of thrombosis and embolism. Only pulmonary emboli which were proved to be present at necropsy are included in the following table.

Occurrence of Emboli

	Carcinoma of the Stomach			Pulmonary Embolus	
	Cases	Thrombosis	Per Cent		Per Cent
Total.....	1,458	45	3.8	12	0.8
Resection.....	496	17	3.4	5	1.2

Chronic.....	819	5	0.5		
Acute.....	458	7	1.5		
Perforated.....	490	14	2.8	4	0.8

In cases of carcinoma of the stomach, thrombosis occurred more frequently in the saphenous and femoral veins of the right side than in those of the left side. Thrombosis was never diagnosed clinically in patients of this group who died of pulmonary embolism. In the cases following appendectomy, thrombosis could not be demonstrated clinically. In one case following operation for carcinoma of the rectum, there was thrombosis of the right saphenous vein on the eighth day, and on the sixteenth day the patient died of pulmonary embolus. In appendicitis, thrombophlebitis occurred much more commonly in cases with infection, and fatal pulmonary emboli occurred only in cases with infection. Thrombosis of the extremities in this group was greater than in previous groups, and it occurred twice as often on the left side as on the right. In carcinoma of the stomach and rectum, infection does not appear to play a great rôle as a causative agent. Intravenous treat-

73. Von Tempsky, Arthur: *Die Lungenembolie nach chirurgischen Eingriffen*, Beitr. z. klin. Chir. **144**:170, 1928.

ment is not a cause. Cachexia and extreme amounts of fat seem to be factors in death of patients from pulmonary embolism.

Nyström⁷⁴ stated that in Sweden 5 persons have recently been operated on, after the manner of Trendelenburg, for the removal of pulmonary emboli. Three patients were operated on by Nyström, with 1 recovery and 2 deaths. The other 2 patients, operated on elsewhere, recovered. In Nyström's patient who recovered, the circulation was stopped for one hundred and four seconds while the clot was removed by means of a suction apparatus. Studies made of this patient two months after operation showed the heart and the large vessels to be anatomically and functionally normal.

Meyer⁷⁵ reported that he had seen 7 pulmonary emboli in a series of 2,182 operations in one year. Six of the patients died so suddenly that operation for emboli was not possible. In a seventh case, the operation was performed but the patient died of pneumothorax produced through a fault in technic. In another case of pulmonary embolism the operation was successful.

Giertz⁷⁶ reported from his clinic in the last six years that there were 7,824 operations and 239 cases of thrombosis or embolism. Of the cases of embolism, 27 were pulmonary and operation was done in 4 cases. Two of these patients recovered. In none of the 4 operations was any anesthetic necessary; the patient was moribund at the time of operation.

Friedel⁷⁷ reported that at the Rudolfs-Spital in Vienna occasion has arisen for doing the Trendelenburg operation 6 times. None of the patients recovered. Friedel pointed out that diagnosis is not always easy. In 2 patients who died, apparently from pulmonary embolism, necropsy revealed that death had been from cardiac causes.

Stegemann⁷⁸ examined Kirschner's patient, the first patient successfully operated on for pulmonary embolism, four years after the operation and found her normal in every way.

DeCourcy⁷⁹ stated that fully 50 per cent of the serious pulmonary complications which occur after abdominal operations are the result of embolism. Advanced age of the patient and incision through the

anterior abdominal wall are two outstanding predisposing factors in postoperative pulmonary embolism. Sepsis appears to be only a contributing factor. Rough handling of tissues, endocrine disturbances with lowered metabolism and venous stasis may be considered as other causes in the development of postoperative pulmonary embolism. The use of Fowler's position, the pillow beneath the knees after gynecologic operations and restriction of movement tend to favor massive thrombosis by retarding venous circulation. DeCourcy advocated the reverse Fowler position after surgically clean operations in the lower part of the abdomen. This position consists of elevating the foot of the bed about 15 cm. and inserting a small, fixed pillow under the small of the back.

[COMPILERS' NOTE.—Pulmonary embolus continues to be one of the most dreaded postoperative complications. Fatal pulmonary embolus fortunately is rare. Many postoperative pulmonary complications undoubtedly are embolic in origin. In our experience, fatal pulmonary embolus occurs too rapidly to consider the question of surgical intervention. The patient who survives the immediate shock often recovers under expectant treatment. The diagnosis of pulmonary embolism, while usually plain, is not always so and may be confused with certain cases of cardiac failure.]

ANESTHESIA

Wymer⁸⁰ described Ombredanne's method of ether anesthesia. A rebreathing apparatus is used in which the exhaled carbon dioxide and ether pass directly into a bag and are reinhaled. The amount of ether used can be determined accurately and is considerably less than that used in the drop method. In one case, 450 Gm. of ether was required by the open method; in a case of the same type only 150 Gm. was required by Ombredanne's method. This lessening of the amount of ether required results in an appreciable decrease in postoperative pulmonary complications.

Melzner⁸¹ reviewed the subject of rectal anesthesia and gave his experience with tribromethanol (avertin). The manufacturers of this drug claim that it does not cause local irritation, that it does not produce unpleasant symptoms and that it is harmless and easily removed. Melzner has used the drug in 100 cases. The dosage used was 0.15 Gm. for each kilogram of body weight given as a 2.5 per cent solution in physiologic solution of sodium chloride. Morphine was given previous to injection. There was no local irritation. Light sleep was produced in from two to five minutes, and deep sleep in from ten to twenty

81. Melzner, Ernst: *Zur Beurteilung der Rectalnarkose mit E. 107 (Avertin)*, Arch. f. klin. Chir. **148**:698, 1927.

minutes following injection. Sleep occasionally lasted ten hours and longer, with no postoperative vomiting. It produced unpleasant mental disturbances in some instances. In one patient, hallucinations lasted twenty-four hours. Complete anesthesia was produced in only 54 per cent of cases and in three cases there was complete failure. Following the administration of the drug, there is an increase in the pulse rate and a fall in blood pressure; the latter, in some instances, is alarming. There were four deaths. Two occurred during anesthesia; one of these patients had a tumor of the brain; the other had a carcinoma of the stomach for which palliative gastro-enterostomy was done. One patient with exophthalmic goiter died six hours following operation and another who had undergone excision of simple goiter, died twenty-four hours postoperatively. In this case, epithelial necrosis in both kidneys was found at necropsy. Melzner advised against the use of this drug.

Martin⁸² was able to produce complete narcosis in 96 per cent of cases by combining scopolamine and a proprietary double salt of morphine and narcotin with tribromethanol. The duration of full narcosis was from one and a half to two hours. The normal dosage is scopolamine, 0.00025 Gm.; proprietary double salt of morphine and narcotin, 0.03 Gm., and tribromethanol, from 0.13 to 0.15 Gm., for each kilogram of body weight. These dosages are varied slightly according to the age, weight and condition of the patient. Martin's series includes 104 cases of laparotomy.

Butzengeiger⁸³ has used tribromethanol in approximately 300 operations, including 200 of laparotomy, and believes that it has some distinct advantages over other forms of anesthesia. It can be given to the patient in bed, and sleep follows naturally; thereby the fear that many patients have of other forms of anesthesia is overcome. Butzengeiger did not have any fatalities. He stated, however, that at present only small doses must be tried and that complete anesthesia is not to be expected in every case.

Nordmann⁸⁴ has had favorable results with tribromethanol in 250 cases and believes that it is a step in advance in methods of anesthesia, although it is too soon to draw definite conclusions.

Sauerbruch⁸⁵ reported three cases in which tribromethanol produced ulceration of the large bowel which resulted in death; he warned against its widespread use until further careful investigation has been carried out.

85. Sauerbruch, in discussion on Butzengeiger: *Arch. f. klin. Chir.* **148**:99, 1927.

Reischauer⁸⁶ reported the case of a patient who died as a result of anesthesia with tribromethanol. Necropsy revealed marked fatty changes in the liver and kidneys.

Kirschner⁸⁷ pointed out that any new method of anesthesia must fulfil certain requirements; namely, that in all cases sufficient anesthesia must be produced and that this must be achieved without any greater risk than that which accompanies the methods of inhalation anesthesia now employed. Neither of these requirements has been fulfilled by tribromethanol up to the present time.

[COMPILERS' NOTE.—Rectal anesthesia with tribromethanol has been widely used in Germany. In a number of clinics it has been found useful and apparently in these clinics bad results have not been experienced from it. However, in an equal number, notably the clinic in Jena, Küttner's clinic in Breslau and Clairmont's clinic in Zurich, the drug is not used any longer because the physicians of these clinics believe it dangerous.]

Air embolism, with the pulmonary vein as the portal of entry, may complicate nearly any surgical procedure on the lung. Graham¹ experienced two fatalities from this source in forty-five operations of cautery pneumectomy, and it has occurred in as simple a procedure as irrigation of an empyema cavity. Brauer² termed the condition arterial air embolism and emphasized its frequency as a complication of artificial pneumothorax. While the cause of the syncope, collapse and death that are occasionally seen during pneumothorax induction is not always clear, it is doubtless often air embolism. Stivelman³ reported seven instances occurring in 162 primary punctures; Forlanini⁴ had twelve in 134, and Sachs⁵ collected twenty-two in 1,122 from the literature.

Sharp distinction must be made at once between this form of air embolism and that in which air enters a peripheral vein, as the jugular or subclavian. In the former, air enters the peripheral arteries and may involve every organ and tissue, while in the latter air passes into the pulmonary arteries and exerts its effects on the lesser circulation and right side of the heart.

In this article are presented certain clinical and experimental data and deductions concerning air embolism from the pulmonary vein. A brief summary of current knowledge is given to introduce each phase

of the subject. Complete reviews of the literature are available elsewhere.⁶

ETIOLOGY

Air may enter the pulmonary vein spontaneously or may be injected.

The venous pressure in the pulmonary circulation is ordinarily less than that of the atmosphere, and should the lumen of a vein be freely opened air is drawn into the blood stream. This has occurred in such operations as pneumectomy, pneumotomy, pulmonary decortication, dissection or probing within the lung and separation of the pleural adhesions. Injection of air or other gases directly or indirectly into the circulation has occurred in the production of artificial pneumothorax. The needle may accidentally enter the lung and one of its vessels, or when the puncture has been accurate and the gas enters the pleural cavity an adhesion between the lung and the wall of the chest may tear and open a pulmonary vein. Air from the pleural cavity may then enter the torn vessel.

Essentially the same type of embolism has been known to arise in other ways: Air that has entered a peripheral vein and has been carried to the right side of the heart occasionally finds its way through a patent foramen ovale into the left auricle.⁷ That the foramen ovale is frequently patent without evidence during life is well known. Herxheimer⁸ found from 20 to 50 per cent patent during routine examination at autopsy; Otto⁹ noted 286 in 1,130 consecutive autopsies in Dresden material, of which 200 admitted a probe only and eighty-six were of comparatively large size; Lubarsch¹⁰ found patency in 25 per cent, and Kaufmann¹¹ in 32.5 per cent.

In 1808, Bichat¹² demonstrated that when air is blown into the lungs of a living animal at a pressure no greater than the maximum expiratory effort of which the animal is capable, provided the pressure is maintained, air will leave the alveoli and enter the pulmonary capillaries. Enough air may thus be forced into the circulation to cause death, and the effect is, of course, the same as though the air had directly entered a pulmonary vein. Ewald and Kobert,¹³ in a painstaking study,

"Ist die Lunge luftdicht?," showed that this phenomenon is not one of alveolar rupture but of escape of air through normal stomas in the alveolar walls when a certain degree of distention is reached. On this principle has been explained the finding of air occasionally in the cavity of the left side of the heart of persons drowned¹⁴ or hanged¹⁵ and of infants who have received strenuous resuscitative measures.¹⁶ Neubürger¹⁷ suggested that the convulsions which sometimes occur in whooping cough are from cerebral embolism, air being forced into the blood stream from the alveoli during a paroxysm of coughing. At autopsy in these cases confirmatory evidence is found in the lesions of the brain.¹⁸

CLINICAL CASES

CASE 1.—A man, aged 42, had an illness of sixteen months' duration. The onset was insidious, with cough, fever, night sweats and progressive loss of weight. The sputum was abundant and fetid, and was constantly negative for tubercle bacilli. The diagnosis was bronchiectasis of the left lung and chronic empyema.

He was admitted to University of Iowa Hospital surgical service. A small empyema pocket in the left side of the chest was drained by rib resection. Some time later, by roentgen examination, a cavity was found in the left lung, and surgical drainage of the cavity was undertaken. With the patient under ethylene anesthesia, a piece of rib was removed at the posterior axillary line over the cavity. The pleural surfaces were found adherent, and an exploring needle, attached to a syringe, was passed into the lung. The resistance offered to the needle by the parenchyma of the lung was increased. At some points air was aspirated freely, at others blood. No pus was found and after a few punctures the attempt was abandoned. As the wound was being closed, the patient suddenly ceased to breathe and heart action could not be detected.

At autopsy, about one hour after death, air was found in large quantities in the blood vascular system. The right side of the heart and pulmonary artery were distended with bloody froth. The left side of the heart was empty. Air was present in the aorta and its main branches, and beads of air were plainly visible in the coronary arteries, the mesenteric arterioles and such small arteries as were exposed by dissection. The veins everywhere were free from air, except for the portal vein and the great veins near the right side of the heart, which contained large amounts. The left lung was fibrous, contracted and adherent to the wall of the chest throughout, except where there was a small empyema cavity. This cavity communicated with the surface through an old thoracotomy wound. After the left lung was removed, the integrity of its bronchial tree was tested by filling it with water. The water returned immediately by way of the pulmonary vein of the upper lobe. In the left primary bronchus was found a papillary carcinoma nearly obstructing the lumen. On section, the lung proved to be fibrotic throughout and was riddled with saccular bronchiectatic cavities. Dissection failed to show a precise point of communication between the bronchial tree and the pul-

monary vein, although a clot of fresh blood was found in a bronchiectatic cavity in the upper lobe at a point roughly corresponding to the site of thoracentesis. The right lung was normal, and observations elsewhere were unimportant.

The diagnosis was: carcinoma of the left primary bronchus, bronchiectasis, chronic empyema, bronchovenous fistula and air embolism from the pulmonary vein.

EXPERIMENTAL WORK

Proof by experiment was sought for the theorem suggested by this case: Given a bronchovenous communication, the pressure relationships within the bronchi and veins in a closed chest during life are such as to transfer air from bronchus to vein. Four dogs were used. A bronchovenous fistula was produced within the intact chest in such a manner that communication could be established or abolished at will and the passage of substances through the fistula could be observed.

Dog 1, weighing 10 Kg., was given positive pressure ether anesthesia. The chest was opened through an intercostal incision on the right and the hilum of the lung was exposed. A glass cannula filled with sodium citrate solution was tied into the pulmonary vein of the lower lobe. Another cannula was fixed in the wall of the accompanying bronchus, and the two cannulas were led out of the chest and connected with a short piece of rubber tubing, temporarily clamped off. The lungs were then inflated to exclude pneumothorax and the chest wound closed tightly about the cannulas. The dog was then allowed to recover consciousness fully.

While the animal was walking about, the clamp was suddenly removed from the connecting tube and communication was established between the bronchus and vein. With the next inspiration, the solution in the cannula passed quickly into the vein and was followed by air, as evidenced by the behavior of a little solution that remained in the bend of the tube. The next two or three inspirations each drew more air into the vein, and then the flow was reversed filling the tube with blood. Almost immediately after the first inspiration the dog appeared uncomfortable, and the hind quarters began to drag; paralysis spread and in a few seconds the dog fell to the floor unconscious. There followed focal and general convulsions, labored breathing, extreme rotation of the eyeballs and wide dilatation of the pupils. At about three minutes, muscular relaxation occurred, respirations became feeble and soon ceased. Heart action continued for a minute or so.

Autopsy revealed that the relations within the chest were normal except for the artificial connection between the bronchus and vein. Quantities of air were contained in the vascular system.

DEDUCTIONS

A bronchovenous fistula may be created in man by the passage of an exploring needle into firmly indurated lung tissue. Given such a communication, the relation of bronchial to venous pressures during inspiration is such as to pass air from bronchus to vein and to give rise to fatal air embolism.

DISTRIBUTION OF AIR IN THE CIRCULATION

Gundermann¹⁹ opened the chest of dogs widely with the animals under positive pressure anesthesia and injected air directly into a

19. Gundermann, W.: *Mitt. a. d. Grenzgeb. d. Med. u. Chir.* **33**:261, 1921.

pulmonary vein. It appeared to him that the air was distributed by the heart evenly and in proportion to the size among the peripheral arteries, until just before death, when because of a weak heart action the branches of the aorta lying near the heart received a larger share. He observed air bubbles immediately entering the coronary arteries and riding there without a tendency to pass on through the capillaries, and he concluded that air cannot pass any capillary bed. Heller, Mager and von Schrötter,²⁰ on the other hand, observed air bubbles travel through the mesenteric circulation, and Beneke²¹ found air accumulated in large quantities in the right side of the heart, when injection had been made into the peripheral arteries.

That position of the body affects in some degree the distribution of the air in this form of air embolism was suspected by Schlaepfer,²² for he noticed that bubbles could be seen in the retinal vessels of dogs only when the head was held up.

EXPERIMENTAL WORK

The distribution of air received into the pulmonary veins in the vascular tree was studied in dogs under varied circumstances of dosage and body position. The manner of inducing embolism was uniform: With the animals under positive pressure anesthesia, the chest was opened and a glass cannula, filled with sodium citrate solution and temporarily obstructed at the outer end, was fastened in the branch of the pulmonary vein from the lower lobe of the lung and led out of the chest. The chest was closed, residual pneumothorax being avoided. The anesthetic was then discontinued and air was injected through the cannula with a syringe at a uniform rate of 25 cc. per minute. At death, or when the animal was killed, a systematic examination was made of the vascular system.

The experiments may be grouped in accordance with the position of the animal. Representative protocols are as follows:

Group 1: Position Horizontal, Sixty-Seven Dogs.—EXPERIMENT 1.—Dog 21, weighing 16 Kg., was placed on the left side in the horizontal position, and an amount of air equal to 3.9 cc. per kilogram of body weight was injected into the pulmonary vein. Death occurred in nine minutes.

At autopsy, the right side of the heart and adjacent great veins were found moderately distended with air. The pulmonary arteries were filled with air; the left side of the heart and pulmonary veins were free. There were a few air bubbles in the coronary arteries and veins. The aortic arch was partly filled with air, but the descending aorta throughout contained none. The carotid, axillary, internal mammary, intercostal and femoral arteries on the right side

20. Heller, R.; Mager, W., and von Schrötter, H.: *Ztschr. f. klin. Med.* **32**: (suppl.) 113, 1897.

21. Beneke, R.: *Verhandl. d. deutsch. path. Gesellsch.* **16**:263, 1913.

22. Schlaepfer (footnote 6, first reference).

held considerable amounts of air, while the corresponding vessels on the left were relatively free. The mesenteric arteries were beaded with bubbles. Air was found only in the femoral, portal, internal mammary and jugular veins.

In other dogs of this survival time the distribution of air was essentially the same. Those dying more rapidly (in from one to two minutes) showed air still in the left side of the heart and confined largely to the arteries. Little was found in the large veins or right side of the heart. Animals living longer than dog 21 (from twenty to thirty minutes) had little or no air in the right side of the heart and veins and reduced amounts in the peripheral arteries. The coronary arteries were regularly free. A constant and striking observation was unequal distribution, for vessels lying uppermost in the body, here in the right side, were always much more abundantly supplied with air. This evidence of air buoyancy

Fig. 1.—Air trap used to study the distribution of air.

was displayed also in the aortic arch. The first portion of the arch lay uppermost and accumulated air from the blood passing through. This air drained off largely into the great vessels of the neck, and the result was to distribute a greater portion of the air to the head, neck and upper extremities than would be indicated from the size of the vessels.

In a few of these dogs, the distribution of air was studied more exactly by interposition of air traps in the blood stream at various points. The air trap (fig. 1) was a small inverted flask with afferent and efferent cannulas. The circulating blood was rendered incoagulable by the intravenous injection of 20 mg. of heparin per kilogram of body weight. The vessel in question was then exposed and divided and the two ends connected with the trap cannulas, the trap being first filled with blood. When adjusted, the trap thus became a part of the vascular system, and by retaining air which passed through the vessel permitted estimation of its appearance time and amount.

EXPERIMENT 2.—Dog 65, weighing 13 Kg., was fitted with traps in both carotid arteries. Three and nine-tenths cubic centimeters of air per kilogram of body weight (50.7 cc.), which is a lethal dose, was injected into the pulmonary vein in the routine manner. Almost instantly after the injection was started air bubbles began to appear in the traps and continued to do so only as long as the injection lasted. The dog recovered; it was killed at one hour.

At autopsy, air was found distributed in the vessels as usual, except that the carotid arteries were free. Twenty-seven cubic centimeters of air was recovered from the traps, i. e., more than half that injected.

EXPERIMENT 3.—Dog 38, weighing 12 Kg., was fitted with traps in both vena cavae, and 3.9 cc. of air per kilogram of body weight (46.8 cc.) was injected into the pulmonary vein. At one minute and twenty seconds, bubbles of air began to appear in the trap of the superior vena cava. No air entered the other trap. Death occurred in ten minutes.

Autopsy showed air to be distributed in the usual manner, except that the right side of the heart and pulmonary arteries were free. Three cubic centimeters of air was present in the trap of the superior vena cava. This amount could obviously not be taken to represent the quantity ordinarily returning to the heart after this dosage of air, since the presence of the traps in the cavae impeded the driving force of the heart to a considerable degree.

Group 2: Position Vertical, Head Down, Sixty-Six Dogs.—Dog 109, weighing 17 Kg., was raised to a vertical position, head down, and 3.9 cc. of air per kilogram of body weight was injected into the pulmonary vein. Death occurred at seventeen minutes.

Autopsy revealed that air filled the coronary arteries and the arteries and veins of the trunk and hind legs. None was found in the vessels of the head, neck and forelegs, nor in the vena cavae, right side of the heart or pulmonary arteries.

In all of these animals, the pattern of distribution was constant. The vessels caudad to the heart alone received air. The coronary arteries contained much more air than with the dog in the horizontal position, and often the blood was entirely replaced by air, giving the vessels the appearance of silver threads. Occasionally, the left ventricle, being inverted, retained a considerable quantity of air indefinitely. No air returned to the right side of the heart.

The observations were corroborated in part by experiments using traps in various vessels.

Group 3: Position Vertical, Head Up, Nineteen Dogs.—Dog 47, weighing 5.5 Kg., was placed in a vertical position, head up, and 3.9 cc. of air per kilogram of body weight was injected into the pulmonary vein. Death occurred in five minutes.

Autopsy revealed that air filled the vessels of the head, neck and forelegs. A small amount was found in the right side of the heart and pulmonary arteries and a few bubbles of air only were contained in the coronary arteries.

In this group of animals again a constant pattern of air distribution was presented, which was complementary in type to that for the group with the head down. Only the vessels taking origin from the aorta cephalad to the heart received air. The coronary arteries were involved to a minimal degree.

DEDUCTIONS

Air that enters the circulation by way of the pulmonary vein follows the course of the blood stream in general but with uneven distribution. Instead of being divided among the vessels in amounts according to their sizes, the air tends to float on the blood and to seek the upper parts of the body. Even where the stream is rapid and violently churned, as in the heart and aorta, air and blood fail to mix thoroughly; the air may remain stationary in a bend of the vessel, or, should gravity so dictate, it may even pass in the direction opposite to that of the blood.

This influence of air buoyancy on the distribution determines distinct differences in various positions of the animal. A typical pattern of embolism with but slight individual variation is found in any given position. Thus, in the dorsal recumbent, horizontal position, air quickly leaves the pulmonary vein and left side of the heart and passes into the aorta. The arch of the aorta is distinctly higher than the descending portion of that vessel and acts as a trap to hold a large part of the air and pass it into the great arch branches. Thus, more than half of the air may go to the head, neck and upper extremities. Distributed in this uneven manner, the air in the form of bubbles is driven to the periphery. The capillaries hinder but do not prevent passage, and after a minute or so air begins to return by the veins of the parts affected to the right side of the heart, whence it is thrown into the lesser circulation. No air succeeds in traversing the pulmonary capillaries but it is held in the pulmonary arterial tree, obstructing the lesser circulation partially and gradually disappearing by excretion into the alveoli and by absorption into the blood and tissues. Air remains longest in the peripheral arteries, sometimes for several hours, for a shorter period in the pulmonary arteries, right side of the heart and great veins, no longer than one-half hour in the coronary arteries and for only a few seconds in the pulmonary veins and left side of the heart. Thus, the period of time that elapses between embolism and death determines largely the position of the air at autopsy.

With the animal in a vertical position, air is distributed only to those parts lying above the level of the heart. Accordingly, when the head is up, the head, neck and forelegs receive the air totally, except for a slight amount in the coronaries; when the head is down, the trunk and hind legs receive the air, and the coronaries are heavily involved.

PHYSIOLOGIC REACTION, TOLERANCE AND CAUSE
OF DEATH

The symptoms in man in air embolism from the pulmonary vein are separable more or less distinctly into two types, neuromuscular and cardiovascular. In a given case, both types may be equally represented, or one may predominate even to the exclusion of the other.

The nervous symptoms are extremely various and occur in different combinations in each instance. The onset may be precipitous with immediate unconsciousness and death, or it may be ushered in more gradually, beginning with dizziness, faintness, local or general paresthesias, aphasia and visual disturbances. More serious symptoms are paraplegia and hemiplegia, blindness, focal and general convulsions, unconsciousness, hyperpnea, Cheyne-Stokes respiration and unequal, dilated and reactionless pupils. Death may occur at any time, and has been known to be delayed as long as six days. When delayed, an unconscious state predominates with periodic convulsions. At any stage, the symptoms may begin gradually to disappear and the patient to recover. Persistent paralyses have occurred.

Cardiovascular symptoms consist in pulse irregularities, asphyxial signs and evidences of gradual or sudden heart failure. Patches of marble-like discoloration are sometimes found on the skin. These symptoms are seen alone when the patient is under general anesthesia and nervous reactions are inhibited, or when the amount of air is overwhelming and nervous effects do not have time to develop. Detailed discussion and illustration of symptoms are given by Schlaepfer.²²

The degree of tolerance in man for air entering the circulation from the pulmonary vein is not known, although it is understood to be much less than that from a peripheral vein. In certain instances, as in the case reported by von Adelung,²³ the amount of gas injected for pneumothorax at the time of air embolism was known, but what part of that actually entered the circulation could not be determined. In animals, Gundermann²⁴ alone has estimated tolerance. Using dogs, he opened the chest with the animals under positive pressure anesthesia and injected air into a pulmonary vein, and found that even 1 cc. slowly introduced was immediately fatal. The unnatural circumstances of the experiments, however, probably rendered the animals abnormally susceptible.

It is generally appreciated that the tolerance of a person for air embolism depends largely on the rate of entrance of air into the circulation.

In air embolism from the peripheral vein the tolerance has been studied experimentally by several investigators. Ilyin²⁴ noted that dogs withstand as much as 2,000 cc. of air injected into the jugular vein at a rate of 30 cc. per minute with 10 mm. of mercury pressure. The dose per kilogram of body weight was not estimated. In twenty-five rabbits, Jehn and Nägeli²⁵ found the maximum tolerance to be 0.89 cc.

per kilogram of body weight; in six cats, 2.5 cc. per kilogram; and of two dogs, one survived 5.3 cc. and one died from 7.7 cc. per kilogram. The rate of the injection was not given. Richter²⁶ stated that in dogs 20 cc. of air produced alarming symptoms and 250 cc. was lethal; in horses, the corresponding amounts were 1,000 and 8,000 cc. No body weights, injection rates or numbers of animals were given. Many other investigators have contributed less accurate data. It is to be concluded that different species present widely different tolerances and among individuals of a single kind there is variation. The values in man are again not known.

The cause of death in air embolism from the pulmonary vein was referred by Gundermann¹⁹ to heart failure, after observing in his dogs immediate myocardial incapacity following the entrance of air into the coronary arteries. He pointed out that heart action ceased too soon to allow involvement of the brain to play a part. Beneke,²⁷ at autopsy in man, found much air in the right side of the heart and pulmonary arteries and suggested that death was due to obstruction of the lesser circulation, as in air embolism arising from a peripheral vein. The fallacy of this assumption was indicated by Gundermann in the fact that an amount of air which is lethal when entering the pulmonary vein is readily tolerated when injected into a peripheral vein. The majority of authors agree with Brauer²⁸ and his school in ascribing death to brain embolism, since nervous symptoms frequently predominate and at death respirations usually cease long before heart action. Wever²⁹ injected air into the carotid artery of dogs and monkeys and produced a symptom complex similar to that of man. The brains of Wever's animals were examined by Spielmeyer.³⁰ Those that survived more than fifteen hours presented focal ischemic necrosis distributed irregularly, chiefly in the cerebral cortex, and characterized by degenerative alterations in the ganglion cells and glial proliferation. The degree was in proportion to the amount of air and to the period of time between embolism and death. The same changes were found in cases in man. Gold³¹ described the brain of a person who died six days after cerebral air embolism, and in addition to the alterations mentioned, indicated edema of the whole brain and petechial hemorrhages in the medulla oblongata and pons.

CLINICAL CASES

Case 1, already described, illustrates the purely cardiovascular type of symptomatology, and case 2, to be described, the neuromuscular type.

EXPERIMENTAL WORK

Physiologic Reaction.—The reaction of the dog to air injected into the pulmonary vein was studied under varied experimental circumstances. The doses, determined according to the body weight, ranged from amounts easily borne to those immediately fatal. Three positions were employed, as in the preceding experiments. The method was the same in all instances:

A cannula was placed in a pulmonary vein. The femoral artery was cannulated and connected with a mercury manometer. With the

FIG. 2 (dog 20).—Injection of air into the pulmonary vein, with the dog in the horizontal position. Moderately severe reaction.

animal under ether anesthesia, respiration and blood pressure were observed, and when they had been constant for three minutes, the ether mask was removed and the dose of air injected into the cannula of the vein at a rate of 25 cc. per minute. The reaction was noted in detail.

Typical protocols are as follows:

Group *a*: Position Horizontal, Sixty Dogs: EXPERIMENT 1.—Dog 20, weighing 16 Kg., received 3.55 cc. of air per kilogram of body weight and displayed a moderately severe reaction (fig. 2).

At one minute thirty seconds, respiration became gasping and irregular; at eleven minutes, more regular, and at fifteen minutes, normal.

At two minutes, the injection of air was complete.

At three minutes twenty seconds, the blood pressure, which had begun to rise with the beginning of the injection of air, reached a maximum of 40 mm. of

mercury above normal. It then fell gradually to a minimum of 30 mm. of mercury below normal at twenty-three minutes. It was commencing to rise when the readings were stopped.

The pulse was regular and strong throughout.

Unconsciousness continued, although no more anesthesia was administered. After one hour twitching contractions of the legs and walking movements began. The muscles were spastic and at times the decerebrate posture of Sherrington was assumed. The dog moaned and howled now and then, although obviously unconscious. No cardiorespiratory irregularities were noted. After four hours, consciousness returned sufficiently to permit vague recognition of surroundings and unsteady walking, but this was temporary and death occurred in deep unconsciousness at five hours twenty minutes.

EXPERIMENT 2.—Dog 28, weighing 22 Kg., received 3.9 cc. of air per kilogram of body weight and presented a severe reaction (fig. 3).

FIG. 3 (dog 28).—Injection of air into the pulmonary vein, with the dog in the horizontal position. Severe reaction.

At two minutes, respirations were gasping. There were periods without breathing. At fifteen minutes, breathing ceased.

At three minutes twenty seconds, the injection of air was complete.

At three minutes ten seconds, the blood pressure, which began to rise with the injection of air, reached a peak of 52 mm. of mercury above normal, and then fell jerkily to 0 at eighteen minutes twenty seconds.

The pulse remained regular and full until the fourteenth minute, when it became increasingly feeble; it ceased at eighteen minutes twenty seconds.

Others of these dogs, receiving smaller doses, showed reactions during the first half hour similar to those of dog 28, but less severe and usually followed by recovery. There was always a period of unconsciousness beyond that to be expected from the anesthetic.

Group *b*: Position Vertical, Head Down, Thirty-Two Dogs: EXPERIMENT 1.—Dog 70, weighing 23.6 Kg., received 1.22 cc. of air per kilogram of body weight and presented a moderately severe reaction (fig. 4).

Respirations were affected at no time.

At one minute, the injection of air was complete.

At ten seconds, the blood pressure rose 20 mm. of mercury, dropped almost immediately and remained about 10 mm. of mercury below normal.

At fourteen minutes, the pulse, thus far regular and strong, suddenly began to skip beats, often two or three together, and blood pressure took wide drops. This irregularity continued twenty minutes and suddenly stopped. The pulse continued normal.

At five minutes, consciousness began to return and ether had to be readministered. At thirty minutes, ether was discontinued and the apparatus disconnected. The dog began to awaken as ordinarily from anesthesia and showed no effects of embolism.

FIG. 4 (dog 70).—Injection of air into the pulmonary vein, with the dog in the head-down position. Moderately severe reaction.

EXPERIMENT 2.—Dog 66, weighing 18.1 Kg., received 1.22 cc. of air per kilogram of body weight and had a severe reaction (fig. 5).

Respirations were normal until the fourteenth minute, when they abruptly failed and represented the last sign of life.

At one minute, the injection of air was complete.

At twenty seconds, the blood pressure was 20 mm. of mercury above normal. It dropped slightly and then rose to a level of from 10 to 15 mm. of mercury above normal. At thirteen minutes, the heart action, which had till then been strong and full, suddenly failed and the blood pressure dropped precipitously to 0 at fourteen minutes.

Dogs in this position showed only cardiovascular symptoms. Heart block was frequent and characteristic and was the cause of death, rather than the gradual myocardial failure seen in the horizontal position.

With large doses, sudden, total block occurred very early; with smaller amounts, total block appeared as abruptly but after from ten to twenty minutes of fairly normal course immediately preceded or not by a few dropped pulse beats, or a period of dropped beats (partial block) came and went without warning, followed by recovery. No heart block was initiated after thirty minutes. In none of the animals were there signs of involvement of the central nervous system. There was no interference with consciousness.

Group *c*: Position Vertical, Head Up, Eighteen Dogs: Dog 48, weighing 9.1 Kg., received 3.9 cc. of air per kilogram of body weight and presented a severe reaction (fig. 6).

At thirty seconds, the respirations were shallow and gasping; they ceased at one minute.

At one minute ten seconds, the injection of air was complete.

FIG. 5 (dog 66).—Injection of air into the pulmonary vein, with the dog in the head-down position. Severe reaction.

At twenty seconds, the blood pressure had risen to 38 mm. of mercury; it dropped immediately to 0 at four minutes.

At two minutes, the pulse became weak, and the heart action ceased at four minutes as the last sign of life.

Other dogs that received smaller doses exhibited less severe reactions, but none recovered. The respirations were almost instantly affected and permanent cerebral injury with unconsciousness occurred with the smallest doses. The heart showed no disturbance until some time after respirations ceased.

Group *d*: Investigation of Blood Pressure Reaction, Ten Dogs: The cause of the initial elevation in blood pressure that appears characteristically in air embolism from the pulmonary vein was investigated. Possible causes for this are direct cardiac effects, action on the central nervous system and action directly on the blood vessels. The last

appeared the most likely, for air accumulates in the peripheral arterioles and capillaries and probably increases resistance to blood flow. The first two possibilities were eliminated by experiment, as follows:

With the animals under ether anesthesia, a cannula was inserted in an intercostal artery, pointing toward the aorta. With the dog horizontal, air was injected through the cannula and intercostal vessel into the descending aorta at a rate of 25 cc. per minute. Various doses of air were employed.

Dog 40, weighing 22.4 Kg., received 3.9 cc. of air per kilogram of body weight (fig. 7).

FIG. 6 (dog 48).—Injection of air into the pulmonary vein, with the dog in the head-up position. Severe reaction.

The respirations and pulse were affected at no time.

The blood pressure commenced to rise immediately after the injection was started and reached 40 mm. of mercury above normal at thirty seconds. This elevation was maintained for five minutes, when the pressure returned to normal. At three minutes thirty seconds, the injection of air was complete.

Autopsy showed no air to have entered the coronary arteries or vessels of the head, neck and forelegs.

Tolerance.—The tolerances for air injected into the circulation at various points were compared:

With the animals under ether anesthesia, the pulmonary vein was cannulated in twenty-one dogs, the jugular vein in twenty-six dogs and

the seventh intercostal artery (descending aorta) in ten. Into each dog was injected an amount of air determined according to the body weight and varied from dog to dog, with the purpose of finding the maximum tolerance dose. The rate of injection was 25 cc. per minute. After four hours the outcome was noted, whether by death or by recovery.

The results are charted in figure 8. Here each of three columns represents the greatest amount of air per kilogram of body weight withstood in one of the forms of air embolism. The figures inserted in each column specify the numbers of dogs used, and the positions of the figures indicate the doses and the fates of the dogs. Thus, the maximum tolerance dose for the pulmonary vein is 1.5 cc. per kilogram, while those for the jugular vein and descending aorta are .76 and .70

FIG. 7 (dog 40).—Injection of air into the intercostal artery (aorta), with the dog in the horizontal position.

cc., or at least fifty times as great. Considerable individual variation is evident.

The tolerance for air injected into the pulmonary vein was determined for various positions of the body, with twenty-one dogs in the horizontal position, seventeen with the head up and thirty-two with the head down.

The results are charted in figure 9, the same method being employed as for the preceding chart. The maximum tolerance dose is 0.5 cc. per kilogram of body weight with the head up, 1.5 cc. or three times as great in the horizontal position, and 3.3 cc. or six and one half times as great with the head down. Individual variation presents itself.

Cause of Death.—The observations recorded concerning the symptomatology and distribution of the air suggest that the cause of death differed in certain body positions. With the head up, the air ascended

and involved the brain massively. Death resulted either early from respiratory failure (embolism of the medulla oblongata) or, later from decerebration.

In the head-down posture, the air ascended caudally. The coronary arteries were affected most seriously. The heart instantly ceased to beat or, with smaller doses, it continued for a few minutes and then underwent heart block. The brain was protected from embolism and played no part in the cause of death.

FIG 8.—Tolerance for air injected into the circulation at various points.

In the horizontal position, the air passed to both brain and coronary vessels. In certain instances, the symptoms preceding death suggested involvement of the brain as the lethal factor; in others, coronary involvement. To test the relative importance of these two factors in this position, experiments were devised wherein the brain was protected from air embolism:

With the animals under ether anesthesia, air traps were placed in both carotid arteries. Both vertebral arteries were ligated. A strand of wire was twisted tightly about the neck, including all structures except the carotid arteries, jugular veins, vagus nerves and trachea. Thus, the only blood supply remaining to the brain was through the

trapped carotid vessels. Three and nine-tenths cubic centimeters of air per kilogram of body weight, which is a lethal dose, was then injected into a pulmonary vein. Seven dogs were used.

Dog 32, weighing 11.5 Kg., did not present symptoms referable to embolism. The animal recovered. At one hour, the dog was killed.

Autopsy revealed that the distribution of air was typical of that of pulmonary vein air embolism in this position, except that the head and neck were free. The traps contained 32 cc. of air.

In one other dog, the result was the same. In five dogs, death occurred within a few minutes after embolism.

FIG. 9.—Tolerance for air injected into the pulmonary vein in various positions.

DEDUCTIONS

These animals were under general anesthesia at the time of the injection of air, and during the first ten to twenty minutes the symptomatic effects of embolism of the higher brain centers were necessarily eliminated. This part of the picture is supplied, however, in the experiments in the section on etiology.

The symptomatology was found to be similar in all details to that in man, and to be separable into two types, i.e., neuromuscular and cardiovascular. Extreme variation in appearance and degree also occurred, even with the same amounts of embolus.

There were two well defined periods in the reaction, acute and chronic. The acute period lasted up to one-half hour and was characterized by disorders of respiration, heart function and blood pressure, together with irritative and paralytic effects in the higher brain centers.

The chronic period presented states of semidecerebration or total decerebration, delirium, semilucid periods and convulsive seizures. Improvement leading to recovery was seen at any stage but was rare after three hours. The severity of symptoms was in proportion roughly to the amount of embolus; death occurred in either period.

The type of symptoms was determined largely by the position of the animal. In the vertical position, head up, the neuromuscular type was dominant, and the only cardiovascular effect detectable was the elevation of the initial blood pressure. In the vertical position, head down, cardiovascular responses alone appeared. With the dog horizontal, both types occurred and in varying proportions but the neuromuscular usually predominated.

A constant symptom was the elevation of the initial blood pressure. Evidence was obtained that this resulted from the accumulation of air bubbles in the peripheral arterioles and capillaries with increased resistance to arterial blood flow.

The tolerance of the dog for air injected into the circulation depends largely on the portal of entry. In the jugular vein or descending aorta more than fifty times as much may be withstood as in the pulmonary vein. In the pulmonary vein tolerance depends on body position, and is least in the head-up position, three times as great in the horizontal and six and one-half times as great in the head-down position.

The fatal effects of air embolism from the pulmonary vein are due to impairment of three vital functions; i. e., cardiac activity by the obstruction of the coronary arteries, cerebral and medullary function by blockage of the arteries of the brain and blood circulation by blockage of the pulmonary arteries. Either the first or the second may be the primary cause of death; the third is never more than contributory. The first is the sole cause of death when the animal is in the head-down posture and the mechanism is by heart block; the second alone causes death when the animal is situated head up, with respiratory paralysis in the early stage or decerebration later; in the horizontal position all three contribute and the first or the second may be primary, depending on the chance distribution of the air embolus.

DIAGNOSIS AND PROGNOSIS

The diagnosis of air embolism from the pulmonary vein has been made without difficulty when sucking was heard at an open vessel or when gas was injected into the chest immediately before the symptoms. Becker,³² Stargardt,³³ Perthes³⁴ and others have been led by the visual

32. Becker, E., quoted from Brauer, L.; Schröder, G., and Blumenfeld, F.: *Handbuch der Tuberkulose*, ed. 3, Leipzig, J. A. Barth, 1923, vol. 2, p. 461.

disturbances in some of these cases to examine the eyegrounds and were able to establish a diagnosis by seeing bubbles in the retinal vessels. A large proportion of the cases, however, have probably remained obscure from lack of direct evidence. Often the portal of entry of air or gas into the circulation was not apparent, nor was there a sucking sound; no heart murmur occurred to point to the diagnosis, as in air embolism from a peripheral vein; an ophthalmoscope has rarely been at hand.

The symptomatology has not assisted greatly in diagnosis, due to confusion with that of other forms of sudden collapse, i.e., internal hemorrhage, surgical shock, heart failure, the syncope that ensues with the rapid removal of much fluid from the pleural cavity and pleural reflex. The last of these, otherwise known as pleural eclampsia or pleural shock, has contributed chiefly to the confusion, for it is believed by many that nerve impulses elicited from the pleura and lung by trauma from an instrument are capable of producing all symptoms seen in air embolism. The nature of such nerve reflexes has been studied. Brodie and Russell³⁵ demonstrated strong vagal responses in animals obtained by stimulation of vagal fibers at the hilum, bronchi and alveoli of the lung. Sauerbruch³⁶ saw sudden heart failure in man immediately following mass ligation at the hilum of the lung or probing within a bronchial fistula. Johnson and Luckhardt³⁷ found that sudden, forceful inflation of the lungs in man and animals results in vagus reflex that profoundly slows the heart and depresses the blood pressure, often fatally, and Johnson and Van Allen³⁸ proved that this reflex originates from the vagus fibers in the lung. Moreover, the experimental work of Capps and Lewis³⁹ indicated the presence of two powerful reflexes, one vagal and resulting in cardiac inhibition and the other vasomotor with dilator influence on the peripheral vessels. These could be obtained separately or at once by irritation of the inflamed but not of the normal pleura. The cardio-inhibitory reflex was in itself insufficient to cause death but the vasomotor effects were frequently not recovered from; both served to lower the blood pressure profoundly. Thus, it is proved that what may be termed pleural reflex exists in both man and animals and that inhibition of the heart rate, peripheral vasodilatation and fall in the blood pressure occur and may result in death. On the other

hand, no matter how profound these effects have been, no one has obtained focal irritative and paralytic phenomena of the brain such as occur commonly in cerebral air embolism. In this connection it is to be emphasized that in the lung inflation phenomenon of Johnson and Luckhardt the cerebral symptoms were shown to be the result of ischemia of the brain and without relation to the vagal reflex.³⁸ Disregarding these facts, two extreme and opposite views are held as to the cause of these obscure cases of sudden collapse following instrumentation of the lung. The majority of authors, as Forlanini,⁴ Saugmann⁴⁰ and Stivelman,³ diagnose pleural reflex and pay little or no attention to the possibility of air embolism, while others, notably Brauer,²⁸ Wever²⁹ and Schlaepfer,²² as consistently ascribe the condition to air embolism.

All characteristic symptoms that have been noted in this form of air embolism failed when the subject was under general anesthesia or when the air entered rapidly and in large amounts, since no opportunity was given for evidence of involvement of the brain. The picture was simply that of sudden heart and respiratory failure.

The diagnosis made at autopsy of air embolism from the pulmonary vein has depended on the demonstration of air in the blood stream or of typical cerebral lesions. Both of these could not appear in the same body, since air remains in the vessels during life a few minutes or hours only and the degenerative changes in the brain from embolism develop only after fifteen hours.³⁰ Thus, patients in whom death occurs between two and fifteen hours after the onset of symptoms are expected not to exhibit at autopsy evidence of air embolism, either in the form of intravascular air or that of secondary changes in the brain. Moreover, very small amounts of air may be lethal in embolism from the pulmonary vein, and even though death occurs at once its demonstration in the peripheral vessels is difficult. Use of the roentgen rays has been proposed for diagnosis.⁴¹

Richter⁴² described a technic for the demonstration of air or gas in the vessels at death which has become standard. Each organ is isolated *in situ* by ligation of the vessel supply, then removed and incised under water. Air escaping from the tissues bubbles up plainly. The heart is managed somewhat more simply, for ligation and removal is dispensed with. The pericardium is opened and held suspended to serve as the dish for water submersion. Objection has been raised to this method as laborious and misleading, for the air may be withheld in the vessels by clots and fail to bubble forth, and the water quickly

40. Saugmann, C.: *Beitr. z. Klin. d. Tuberk.* **31**:571, 1914.

42. Richter, M.: *Gerichtsärztliche Diagnostik und Technik*, Leipzig, S. Hirzel, 1905.

becomes bloody and obscures the tissues. Moreover, direct observation of the vessels serves to detect even very small amounts of air, since the smaller arterioles are translucent enough to show air bubbles distinctly and the air in larger vessels, heart, cavae and aorta, is present in the form of froth and escapes as such plainly when the lumen is opened.

It is well known that little significance can be placed on finding air bubbles in the cerebral vessels at autopsy, unless great care has been taken in exposing the brain. In lifting off the skull cap, as it is routinely carried out, cortical vessels are stretched and ruptured and air is sucked from the atmosphere into their lumina.

Differentiation at autopsy of the type of air embolism has depended on three things. 1. The vessel that served as portal of entry is sought. 2. The distribution of the air is determined, the fact being borne in mind that the lesser circulation acts as an effectual barrier to air bubbles. Thus, if air was found in the left side of the heart or the peripheral arteries, the case was one of embolism from the pulmonary vein; if only in the large veins, right side of the heart and pulmonary arteries, it was embolism from a peripheral vein. One exception has pertained to this; a patent foramen ovale may allow air to pass from the right to the left side of the heart and differentiation is prevented. 3. The typical cerebral degenerative lesions are sought for and indicate the pulmonary vein type of embolism, unless there is a patent foramen ovale.

It has been emphasized that fallacious conclusions may result from the presence of putrefactive gases in the blood at autopsy. Dyrenfurth⁴³ found by actual measurement that within twenty-four hours amounts of gas up to 0.25 cc. may be present in the heart cavity, and that this may increase during the next few days to 4 cc. In air embolism from a peripheral vein there was regularly as much as 7 cc., but this is probably too high for embolism from the pulmonary vein, where smaller amounts are lethal. Dyrenfurth⁴⁴ devised a method for the qualitative test of these gases, to rule out the putrefactive. Simmonds⁴⁵ recommended culture of the heart blood for the presence of gas-forming organisms, for the same purpose.

Prognosis has been uncertain. Usually, the return of consciousness has indicated improvement leading to recovery, but in some cases consciousness has been recovered only for relapse to occur. In recovery after pronounced symptoms, focal paralyses lasting as long as six months have been seen.⁴⁶

EXPERIMENTAL WORK

Diagnosis.—A characteristic sign of air embolism from the pulmonary vein, noted practically always in these experiments, was immediate elevation of the arterial blood pressure. The most frequent degree of rise was from 30 to 40 mm. of mercury, but often the initial pressure was more than doubled. The elevation was maintained as long as air continued to be injected and usually also for a minute or two afterward. Even exceedingly small amounts of air produced detectable hypertension. In air embolism from the peripheral vein, on the other hand, initial depression of the blood pressure is the rule. These opposite effects are illustrated in the following experiment.

FIG. 10 (dog 6).—Injection of air into the pulmonary vein, followed in thirty minutes by the injection of air into the jugular vein (graphs superimposed).

Dog 6, weighing 8.4 Kg., was fitted with cannulas in both pulmonary and jugular veins. The femoral artery was connected to a mercury manometer and the normal blood pressure level was recorded. Then a small amount of air (2.2 cc. per kilogram) was injected into the pulmonary vein and the blood pressure reaction noted. Forty-five minutes later, when the pressure was again at a normal level, the same amount was injected into the jugular vein, and the reaction again noted.

The two blood pressure curves thus obtained are compared in figure 10 by superimposition. One is seen to be the reverse of the other.

A second characteristic sign of air embolism from the pulmonary vein is elicited as follows: A stab cut is made through the skin of a part of the body that is uppermost and bleeding is produced. Bubbles of air will stream out distinctly with the blood. The test should be made within fifteen minutes after embolism.

Prognosis.—Prognosis in air embolism from the pulmonary vein in the dog was possible within certain limits: 1. The severity of the symptoms depended in general on the amount of air entering the circulation. 2. Primary respiratory failure was looked for only within the first ten to fifteen minutes; primary heart failure, within half an hour. 3. Unconsciousness, when continued longer than half an hour, indicated serious cerebral involvement.

CLINICAL CASES

Case 2 illustrates the use of the blood pressure reaction in the diagnosis of air embolism in man.

CASE 2.—A white woman, aged 51, presented an illness of seven months' duration. The onset was sudden, with chills, fever and pain in the left side of the chest. Cough developed and fever continued for three weeks. There had been continuous cough and intermittent periods of fever since then. There was 250 cc. of foul sputum daily, which was negative for tubercle bacillus. A moderate loss of weight and strength occurred. The diagnosis was chronic abscess of the left lung.

The patient was admitted to University of Iowa Hospital, surgical service. Iodization of the bronchial tree showed a large filling in the center of the left lung, extending laterally to within 2 cm. of the pleura. This was interpreted as an abscess cavity.

On two occasions attempts were made to reach the abscess with an exploratory needle, without success. The third attempt was as follows: With the patient under local anesthesia, the third rib was resected in the anterior axillary line, which was a point shown by fluoroscopy to overly the abscess closely. The pleura was found free, and the wound was packed with gauze to produce adhesions. Four days later, the pack was removed and exploration was performed without anesthesia, the patient sitting semi-erect. A large hypodermic needle, attached to a syringe, was passed perpendicularly through the rib bed into the lung. The parenchyma was found to be tough. Nothing could be aspirated, except that at one point blood was freely drawn and at another air. The puncture was repeated, and at a depth of 5 cm. the patient started to cough. The needle was withdrawn. She raised a little bright frothy blood and continued to cough urgently. She experienced a prickling sensation over the body surface and became unable to speak. Dyspnea developed and, at about one minute, unconsciousness. The pulse rate was 66, and was slightly irregular. The color was somewhat cyanotic. At about ten minutes (accurate time is not kept at such emergencies) the blood pressure was taken and found to be 180 systolic and 80 diastolic; at twenty minutes, 162 systolic and 76 diastolic; at thirty minutes, 152 systolic and 70 diastolic; at forty minutes, 140 systolic and 68 diastolic; at fifty minutes, 130 systolic and 65 diastolic, and seventy-five minutes, 125 systolic and 65 diastolic. Consciousness returned at thirty minutes and with it speech; at this time it was noted that the entire left side of the body was paralyzed and with hyperactive tendon reflexes. There was no anesthesia. The eyegrounds were normal. At forty-five minutes, the paralysis began to disappear and cleared at one hour. A sensation of heaviness persisted in that side of the body. Dyspnea gradually disappeared. After one and one-half hours the condition was normal, except for the pulse rate, which was 120.

It was thought that air embolism from the pulmonary vein was the cause of the condition, since: 1. Needle puncture in a sclerotic lung is known (case 1) to be capable of producing a bronchovenous fistula, and such a communication permits air to be inspired into the circulation. Here a bronchus and blood vessel are known to have been pierced in a sclerotic lung. 2. During the height of the reaction the blood pressure was found markedly elevated, and in no other form of sudden collapse, save cerebral hemorrhage, is this seen. 3. The symptoms were chiefly those of transient cerebral dysfunction characteristic of air embolism of the brain.

DEDUCTIONS

The diagnosis of air embolism from the pulmonary vein is assisted by two phenomena, readily elicited:

1. Initial elevation of the blood pressure: In the dog, this lasts as long as air continues to enter the circulation and heart action is maintained. Even very small amounts of air produce noticeable elevation. In man, the reaction is described, and here the elevation was maintained about one hour. The presence of this phenomenon in cases of sudden collapse with instrumentation of the lung rules out air embolism from a peripheral vein, pleural and vagal reflex, hemorrhage and traumatic shock. Its transiency rules out cerebral hemorrhage.

2. "Air bleeding": In air embolism from the pulmonary vein, the peripheral capillaries in the upper parts of the body contain bubbles of air, and these flow plainly out with the blood from a wound. A small stab incision serves to demonstrate this. The phenomenon is pathognomonic.

Prognosis is difficult; it depends on appreciation of the amount of air embolus, severity of symptoms and the time interval.

PREVENTION

Measures to insure against air or gas embolism during the administration of artificial pneumothora, particularly at the initial filling, have eliminated much of the danger. Thus, there is the incision method of Brauer,⁴⁷ employment of a blunt needle, manometer control, etc. The accident occasionally takes place, however, even in the best hands.

During the irrigation and probing of pleural fistulas, it has been advocated⁴⁸ that no injury, either by direct trauma or by stretching, be inflicted on the pleural surface or pleural adhesions. Instances of shock following such procedures have been accompanied by bleeding as evidence of damage to vessels within the sinus.

Spontaneous suction by a pulmonary (or other) vein of air from the outer atmosphere is prevented with certainty by causing the patient to breathe under positive pressure at the time, as demonstrated by Tiegel in 1907.⁴⁹ The principle of the apparatus necessary for this purpose is illustrated in figure 11.

EXPERIMENTAL WORK

Various measures that might be expected to prevent spontaneous air embolism from the pulmonary vein were tested in the dog, (1) under the conditions of external venous fistula and (2) under conditions of bronchovenous fistula.

FIG. 11 (dog 50).—Pulmonary vein fistula; temporary protection against air suction by the injection of epinephrine.

External Fistula.—(a) Positive Pressure Breathing, Two Dogs: Dog 49, weighing 8.5 Kg., was anesthetized and fitted with a pulmonary vein cannula. Placed in the horizontal position, positive pressure breathing was applied.

At 20 cm. of water pressure, the cannula was opened. The blood from the vein flowed freely out, both in inspiration and in expiration.

At 17 cm. of water pressure, the bleeding was less free.

At 14 cm. of water pressure, bleeding occurred during expiration, and the column of fluid in the cannula remained stationary in inspiration. At 11 cm., the column of fluid was stationary in expiration and dropped toward the vein slightly in inspiration.

At 8 cm., the fluid meniscus appeared above the surface of the chest in expiration and dropped below in inspiration.

At 5 cm., the fluid remained always below the surface of the chest but embolism did not occur.

49. Tiegel, M.: Mitt. a. d. Grenzgeb. d. Med. u. Chir. 3:789, 1907.

At 3 cm., air was drawn freely through the cannula, and the animal died of air embolism.

(b) Intravenous Injection of Epinephrine, Four Dogs: Dog 50, weighing 5.8 Kg., was placed under general anesthesia, in the horizontal position, and was fitted with a pulmonary vein cannula and a femoral blood pressure recording apparatus. The normal pressure was recorded, and then 0.5 cc. of epinephrine hydrochloride was injected intravenously (fig. 11).

At injection, the blood pressure started to rise.

At two minutes, when the pressure was 74 mm. of mercury above normal, the cannula was opened and found to bleed freely.

The pressure continued to rise and then fell gradually with constant tendency to bleed from the cannula.

At four minutes ten seconds, when the pressure was 72 mm. of mercury above normal, equilibrium was reached. As the pressure fell further the meniscus in

FIG. 12 (dog 111).—Injection of air into the pulmonary vein, with the dog in the head-down position. Illustrating the fatal effect of resuming the horizontal position too soon.

the cannula dropped, and at six minutes thirty seconds, at 28 mm. of mercury elevation, there was sucking of air into the vein, and the dog died from embolism.

In other dogs, the effect was similar, although the blood pressure values were different in each case. Ephedrine was found to act in the same manner.

Bronchovenous Fistula.—(a) Positive Pressure Breathing, One Dog: In dog 51, weighing 6.9 Kg., while under general anesthesia, a bronchovenous fistula was created as in dog 1 (section on etiology) and the communication was kept blocked at first by clamping the U-tube. Positive pressure breathing was applied. At 10 cm. of water pressure, the clamp was removed and patency of the fistula was established. Air passed immediately from bronchus to vein, and the dog died.

(b) Negative Pressure Breathing, One Dog: Dog 52, weighing 7.5 Kg., was treated in a similar manner to dog 51, except that negative pressure breathing

was administered. At 24 cm. of water pressure, the clamp was removed from the U-tube. Air passed rapidly from the bronchus to the vein. The dog died.

(c) Intravenous Injection of Epinephrine, Three Dogs: Dog 53, weighing 9.2 Kg., was fitted with a bronchovenous cannula and a femoral blood pressure recording apparatus. The normal pressure was determined and then 0.5 cc. of epinephrine hydrochloride was injected intravenously.

At injection, the blood pressure began to rise.

After one minute and fifty seconds, with the pressure 56 mm. of mercury above normal, the U-tube was released. The venous blood flowed quickly toward the bronchus.

The pressure continued to rise and then fell gradually, with a constant tendency to bleed from the vein.

After four minutes, the pressure reached 14 mm. of mercury above normal and air was drawn with each inspiration from bronchus to vein, with death.

A similar, transient protection against embolism was seen in the other dogs.

Bronchus Block, Three Dogs: Dog 54, weighing 10 Kg., was fitted with a bronchovenous cannula. A small rubber bag connected with a rubber tube was introduced by bronchoscope into the primary bronchus on the side of the cannula. By inflating the bag suddenly during expiration, the bronchus was blocked and a negative pressure established in the peripheral bronchi in inspiration.

The bronchovenous cannula was released; no air passed into the vein. The bronchus block was released; fatal air embolism immediately took place.

A similar result was seen in the other dogs.

DEDUCTIONS

Spontaneous air embolism from an external fistula of the pulmonary vein was prevented in dogs by two means: (1) Positive pressure breathing (Tiegel), with pressure as low as 5 cm. of water; pressures above 14 cm. of water caused the vein to bleed. (2) The intravenous injection of epinephrine or ephedrine; the protection lasted only while the blood pressure remained above certain levels, which was only a few minutes. Accompanying this was a tendency to bleed from the vein.

Spontaneous embolism from a bronchovenous fistula in dogs was prevented by two means: (1) The intravenous injection of epinephrine or ephedrine; the effects were the same as in external fistula. (2) Bronchial block; protection lasted as long as the block was maintained, and without tendency to bleed from the vein. The use of positive pressure or negative pressure breathing afforded no protection but rather encouraged embolism.

TREATMENT

Consistent benefit in air embolism from the pulmonary vein has not been obtained experimentally or clinically by any form of treatment. Cardiorespiratory stimulants and intracardiac injections of epinephrine

have had no effect. Gundermann¹⁰ exposed the heart in dogs and aspirated and massaged the ventricle but could not rescue any one. He explained his failure by indicating the cause of heart failure as myocardial ischemia, necessarily resistant to any artificial stimulant short of reestablishment of the coronary circulation. Reyer and Kohl⁵⁰ suggested that the person's head be lowered after embolism, in order to bring additional blood to the brain, but this has not proved of assistance.

EXPERIMENTAL WORK

Two measures appeared of likely value in treatment, as indicated by the aforementioned experimental observations, i.e., artificial respiration and the use of the head-down position preliminary to air embolism.

Artificial Respiration, Seven Dogs.—These experiments were carried out in the following manner:

Each dog was placed under general anesthesia in the horizontal position, and a pulmonary vein cannula was inserted. Continuous intratracheal insufflation of air, according to the original principle of Meltzer and Auer,⁵¹ was instituted, and then a measured dose of air was injected into the pulmonary vein at a rate of 25 cc. per minute. The outcome was noted, whether by death or by recovery at four hours. The amounts of air were varied, to determine the maximum tolerance dose.

The maximum tolerance dose was 1.5 cc. per kilogram, which is the same as that found without artificial respiration in this position.

Vertical Position, Head Down, Thirty-two Dogs.—Experiments have been described in the section on tolerance (fig. 9) which indicate that, when the dog is in a vertical position, head down, the maximum tolerance dose is 3.3 cc. per kilogram of body weight, or two times that in the horizontal position.

Vertical Position, Head Down, Plus Artificial Respiration, Fifteen Dogs.—The artificial respiration was combined with the head-down position, described in the two previous experiments. The maximum tolerance dose for air injected into the pulmonary vein was found to be 5 cc. per kilogram of body weight or 50 per cent greater than with the head-down position alone.

This increased tolerance to air embolism was obtained only when artificial respiration was maintained at least one-half hour and when the position was held for one hour or more. The latter requirement is emphasized by experiment:

Dog 111, weighing 12 Kg., under general anesthesia, was placed in a head-down position and given 5 cc. of air per kilogram of body weight into the pulmonary vein, and the reaction was noted (fig. 12).

At thirty-eight minutes, recovery from the embolism seemed complete. The anesthetic had been discontinued and the dog had regained consciousness. The

51. Meltzer, S., and Auer, J.: J. Exper. Med. **11**:622, 1909.

table was lowered to the horizontal position. Immediately, the blood pressure rose slightly and then dropped steadily to 0 at forty-seven minutes.

At autopsy, it was found that air that had accumulated in the large trunk and the arteries of the hind legs had passed backward against the blood stream, ascended the aorta and reached the branches leading to the head and the coronary arteries. This retrograde embolism had obviously occurred at the time of change of the animal's position.

This occurrence of retrograde embolism on change of body position was demonstrated in two other dogs by means of air traps inserted in various vessels.

DEDUCTIONS

Treatment for air embolism from the pulmonary vein by artificial respiration (intratracheal insufflation of Meltzer and Auer) is of assistance only when the animal has been placed in a steep, head-down position before the onset of embolism. The tolerance for air embolus

FIG. 13.—Cross-section of the thoracic wall and underlying lung with exploring needle in place. Illustrating the mode of formation of a bronchovenous fistula by needle puncture.

is then 5 cc. per kilogram of body weight, which is distinctly greater than under any other circumstances tested and is ten times as great as in the most susceptible circumstance, i.e., with the head up.

Artificial respiration must be continued for half an hour and the head-down posture for one hour in order to obtain the beneficial effects.

COMMENT

Air embolism from bronchovenous fistula is a complication demanding consideration in exploratory needle puncture of the lung, judging from the evidence of cases 1 and 2. In the parenchyma of the lungs the pulmonary veins lie in close proximity to bronchi, and transfixion of both vein and accompanying bronchus by the needle leaves defects in their walls at adjacent points (fig. 13). If, then, the parenchyma is

consolidated and inelastic, as it frequently is when such exploration is made, the pathway may remain temporarily patent. Likewise, a broncho-venous fistula may form readily in the case of a pulmonary cavity containing a vein in its wall, where a tangential needle thrust could tear the thin partition separating the lumen of the vein from the cavity. Given a patent bronchovenous communication, the vein becomes a branch of the bronchial tree and receives air during inspiration as voluminously as does any bronchial branch of like caliber. Here the person literally breathes into his circulation. The autopsy in case 1 revealed hundreds of cubic centimeters of air in the blood vessels. Such a mechanism may account for many of the obscure instances of sudden collapse following thoracotomy.

The extreme points of view commonly held as to the cause of these obscure complications following lung instrumentation, ascribing it entirely either to air embolism or to pleural reflex, are not justified by the available clinical and experimental evidence. That both entities exist as such and may occur in man and animals is established beyond reasonable doubt, as we have outlined, and differentiation must be made in diagnosing each case. Symptoms of irritation or paralysis of the higher brain centers point to embolism, but in the presence of cardiovascular symptoms alone either of the causes may be in play.

Differential diagnosis is assisted greatly by examination for one or both of two phenomena, i.e., sudden blood pressure alteration and "air bleeding." Marked depression of the blood pressure is seen in pleural reflex and other forms of shock, while elevation is characteristic of air embolism from the pulmonary veins. "Air bleeding" is, of course, pathognomonic of the latter. These signs are obtainable with instruments usually at hand and with no unusual amount of skill.

Air embolism from the pulmonary vein in its various forms is preventable. When there is a possibility of embolism occurring from external fistula of the vein, the use of positive pressure breathing may be relied on to eliminate the negative intrathoracic pressure and the capacity of the thoracic veins for suction. The Tiegel method (fig. 14) is perhaps the best, being simple and well tolerated by the conscious patient. Its principal advantage over other apparatus of the sort is the freely open breathing outlet, for submergence under water is used to procure pressure and there is no choking sensation produced as occurs with the spring valve devices, which elevate the pressure within the mask by obstruction to the outlet. Moreover, the water submersion principle sets the pressure desired and insures against accidental overdistention of the lungs. The pressure used is slight, from 8 to 10 cm. of water.

When there is a possibility of embolism from bronchovenous fistula, certain and controllable means of prevention are obtained only by

blocking the bronchus leading to the affected lung during the operation. The technic for this in man has not been developed but should be comparatively simple and without necessity of bronchoscopy. A fine catheter fitted at the end with a small rubber bag may be passed through the anesthetized larynx and into the bronchus under fluroscopic control, as in the Iglauer⁵² method for iodization. The use of epinephrine to raise the pulmonary intravenous pressure prevents spontaneous suction by the veins but the effect is too transient to be practicable.

The treatment for air embolism is of little avail. The embolized vital centers cannot be well reached by medication and there is no way of removing the air lodged in the vessels. Anoxemia may be prevented and distinct benefit obtained by the use of artificial respiration, as carried

FIG. 14.—Positive pressure breathing apparatus applied to man, according to Tiegel. The air is supplied by tanks to the breathing mask and bag, and the exhaust air is carried out by a tube under water. The depth of the outlet under water determines the pressure breathed.

out in the experiments reported; this is not applicable to clinical experience, as only the principle of continuous intratracheal insufflation is desirable. Any procedure for administering artificial respiration which entails increasing the chest movements is likely to add to the air embolism and should be avoided. Once air embolism has occurred, it is of no benefit to institute the Trendelenberg position. The patient should be allowed to lie in the original position quietly and fight his own battle.

52. Iglauer, S.: Injected Iodized Oil in Roentgen-Ray Diagnoses of Laryngeal, Tracheal and Broncho-Pulmonary Conditions, *J. A. M. A.* **86**:1897 (June 19) 1926.

When an operation is contemplated in which there is a possibility of air embolism occurring and when certain means of prevention are not at hand the following procedure is advocated:

During the stage of the operation in which embolism is likely to occur, the patient is placed in a steep Trendelenberg position. The blood pressure is taken every minute or so, to warn of complications and indicate immediate interruption of the operation. If a sudden, marked elevation points to embolism, the diagnosis may be confirmed by eliciting "air bleeding," and the patient must then be maintained in the head-down posture for about two hours, to obviate shifting of the air to other parts of the body (coronary and cerebral vessels). Oxygen may be administered with a tent or other efficient passive methods.

SUMMARY

The subject of air embolism from the pulmonary vein is considered in this paper as to etiology, distribution of the air in the circulation, physiologic reaction, tolerance, cause of death, diagnosis, prognosis, prevention and treatment. Under each of these captions is given a review of the present knowledge and original clinical and experimental observations and deductions.

Particular emphasis is placed on the following conclusions:

1. Bronchovenous fistula may be produced by simple thoracentesis and may form a portal of entry for air into the pulmonary veins.
2. Gravity is a determining factor distributing air in the blood circulation.
3. Embolism of the heart (coronary) and brain are the vital effects. The position of the animal determines which of these are primary in a given case.
4. Tolerance for embolism is greatest when the head of the animal is well depressed and least with the head up.
5. Diagnosis is aided by two characteristic and easily elicited signs, i.e., elevation of the initial blood pressure and "air bleeding."
6. Prevention is certain by employing positive pressure breathing, when an external venous fistula is present, or by bronchial block, when a bronchovenous fistula exists.
7. Treatment, although effective under ideal circumstances, is not practical.

EXPERIMENTAL PEPTIC ULCER *

JAMES C. McCANN, M.D.

Fellow in Surgery, The Mayo Foundation
ROCHESTER, MINN.

REVIEW OF THE LITERATURE

A consideration of the numerous methods of procedure used in the experimental study of peptic ulcer shows that experimental ulcers may be grouped under a few general headings: (1) resulting from a deficient blood supply to the gastric mucosa; (2) produced by the action of bacteria; (3) resulting from the action of toxic agents; (4) resulting from trophic and glandular disturbances, and (5) produced by the action of the digestive juices.

Prior to Virchow's time, experimental studies of the problem had not been carried out. Indeed, a clear recognition of peptic ulcer as a distinct pathologic and clinical entity was not achieved until comparatively late in the progress of medical science. Galen, Celsus and other ancient investigators, presented vague and doubtful references to the ulcer in their descriptions of *passia cardiaca*, *hematemesis* and *melena*. The post-mortem examinations of the sixteenth century, stimulated by the general revival of original investigation, resulted in many descriptions of ulcer and cicatrices of the stomach. Bonetus (1679) published in the *Sepulchretum* one of the earliest recorded cases of perforating ulcer, which was observed by John Bauhin; other cases were described in the next century by Donatus, Courtial, Littre, Shenck and Morgagni. Matthew Baillie (1793) published the first accurate study of the anatomic peculiarities of ulcer; he republished the work later with three engravings and clinical data, but it had little influence on contemporary medical thought. A valuable description of the clinical syndrome, including nearly all the symptoms now recognized as characteristic of the malady, was published by John Abercrombie (1824). Cruveilhier (1829-1835) was the first to differentiate clearly ulcer of the stomach, carcinoma of the stomach and ordinary gastritis. He gave a clear anatomic and clinical description of the disease suggesting, as its primary cause, preceding gastritis. He anticipated the modern view expressed by Nauwerck¹ and supported by the studies of Konjetzny²

and others, that gastritis might be the primary condition and the basis of the formation of ulcer. The other modern view, that hemorrhagic erosions establish the basis for a subsequent ulcerative process, was first expressed by Rokitansky³ in his description of seventy-nine cases.

VASCULAR SUPPLY

Historically, the first groping toward an explanation of the cause of ulcer was the concept of vascular insufficiency. Theory preceded experiment and outlined its development. Virchow⁴ announced his theory that vascular infarction was the primary etiologic factor in causing the formation of ulcer in the stomach. He visualized an ulcer as local ischemic necrosis induced by the embolic occlusion of a vessel; this vascular lesion mechanically removed the alkalinizing influence of the blood, and permitted the local destruction of the gastric wall by the corroding hydrochloric acid. The typical conical shape of the ulcer and its eccentric perforation of the serous coat depended, he believed, on the conical distribution of the tuft of vessels arising from the occluded eccentric arterial rootlet. Janeway⁵ presented to the New York Pathological Society a clinical case of ulcer with a fibrinous plug in a branch of the gastro-epiploic artery leading to the ulcer; a source of the plug was not found. Cohnheim,⁶ in reviewing the old authorities, recalled Klebs'⁷ belief that local ischemia due to spastic contraction of the arteries furnished the basis for ulceration; that Virchow attributed it to disease of the vessels, particularly embolic occlusion; that Günsburg⁷ thought impediments to the escape of venous blood acted as a cause; that Key⁷ held that mechanical hyperemia, caused by abnormal contraction of the gastric musculature, might cause local hemorrhage leading to the formation of the ulcer, and that Quincke believed general anemia to be a significant factor.

Embolus.—Experimental study of these hypotheses was first attempted by Panum⁸ and Cohnheim.⁶ Accepting Virchow's theory, Panum injected an emulsion of wax into the central end of the femoral artery of dogs; multiple small hemorrhagic infarcts and ulcers formed in

the stomach. However, the dogs died within twenty-four hours from widely disseminated emboli, so that the ultimate course of these ulcers was a matter of conjecture. Cohnheim injected lead chromate suspension into the gastric branches of the splenic artery, which caused large ulcers with precipitous walls on the second day; several small ulcers persisted into the second week, and complete healing occurred in the third week. In subsequent studies, Payr⁹ and Grossi¹⁰ injected a suspension of bismuth subgallate in sterile water into the gastric veins of twenty dogs, which caused submucous hemorrhage and acute ulcerations. Chessine and Feldmann,¹¹ injecting a 10 per cent emulsion of bismuth subgallate, produced infarcts of the mucosa, but only when they induced concurrent secondary anemia (hemoglobin 40 per cent) by the intravenous injection of chloral hydrate and phenylhydrazine; all ulcers were healed in thirty days, one showing cicatrization. Ivy¹² used finely divided emboli of animal charcoal, which gave negative results after injection into the gastro-epiploic vessels; however, using lead chromate and pigments, he produced ulcers which he interpreted as of toxic origin. Greggio¹³ and Bolton¹⁴ quoted other experiments on the injection of emboli which produced variable results: Sapiejko used lycopodium; Kobayashi and Nauverck used mycotic emboli; Vigliani used a "coagulating substance"; Rosenbach and Exner injected liquid paraffin and cultures of staphylococci into the gastro-epiploics; Shridde used fat emboli; Klebs and Welti used emboli formed from blood corpuscles and pigment granules, and Prevost and Cottard introduced tobacco into the aorta of a rabbit. Wilkie,¹⁵ interpreting the hematemeses that occasionally follows abdominal operations as due to retrograde emboli from omental thrombosis, injected solid particles of sterile oil into an omental vein. These particles impacting in the smaller venous branches caused submucous erosions and definite infarctions of the stomach, with associated infarcts of the spleen and liver. Greggio cited other studies, with the

omentum: Sapiejko burned it, and Eiselberg, Friedlich, Pavy, Schiff, Matthes and Gibelli ligated it, all with uncertain or negative results.

Ligation of Vessels.—These unsatisfactory methods of study were supplanted by ligation of vessels. Littbauer¹⁶ found the anastomosis of vessels so free that a third of the blood supply to the stomach could be cut off without the formation of ulcer. Turck¹⁷ ligated all the vessels of the stomach and produced erosions. Fenwick¹⁸ failed to produce lesions by ligating only a few veins, but by tying most of them and injecting the portal vein with tincture of perchloride of iron, he produced hemorrhages and ulcers. Bolton quoted Mueller, Pavy, Roth and Litten as obtaining negative results from ligature of the larger arteries. Interference with the blood supply associated with injury to the mucosa was studied by Littbauer; he tied all the vessels in a given portion of the stomach, excised a piece of mucosa from that area and fed dilute hydrochloric acid; he procured ulcers in only two of eight experiments. Clairmont,¹⁹ Greggio²⁰ and Matthes²⁰ performed similar experiments, cauterizing the borders of the ulcer with hydrochloric acid, and found that ulcers formed easily in the pyloric region but not in the cardiac region. Yano²¹ found that whereas ligation of the gastro-epiploic arteries had no effect on the fundic mucosa, ligation of the gastric or pyloric artery led, as shown by intravenous injections of dye, to localized nutritional disturbances in the "Magenstrasse" of Waldeyer and Aschoff.

The studies on vascular occlusion in relation to the formation of ulcer suggested to Berlet²² a possible relationship between the anatomic distribution of the vessels and the site of greatest ulcer incidence. He injected the gastric arteries of twenty cadavers with a solution of gelatin containing red lead. Roentgen studies demonstrated that the blood

supply to the pyloric region was much more sparse than that to the other parts of the stomach. He inferred that this predisposed the region to circulatory disturbances, rendering it much less capable of developing compensatory collateral circulation. Reeves²³ found that the vessels in the submucosa of the lesser curvature are smaller and longer, without as free anastomosis as in the other regions of the stomach; also that they are tortuous, with constantly increasing resistance to the blood stream. In the first part of the duodenum there are relatively few vessels in comparison with other parts of the duodenum. He concluded that these vessels are more prone to occlusion by emboli and may play an important part in the production of ulcer by hematogenous infection.

Occlusion of Vessels.—The theory sponsored by von Bergmann,²⁴ that spastic contraction of the arteries causes local ischemia which is the starting point for digestion by the gastric juice and subsequent ulceration, has met with considerable favor among German investigators. Westphal,²⁵ trying to prove the spasmogenic theory of Klebs and von Bergmann, injected large subcutaneous doses of pilocarpine, with and without physostigmine, into rabbits. This produced ulcers and erosions which he considered to be the result of spastic muscular contraction due to extreme vagal irritation. His experiments with cats, dogs and guinea-pigs were not so successful. With the stomach of the rabbit exposed, he observed long continued, spasmodically increased peristalsis, followed by cyanosis and pallor; snow-white specks appeared suddenly on the mucosa in which a dark center occurred. The anemic foci he believed to be due to vascular spasm with impoverishment of the blood supply to the mucosa. On the basis of the lesion ranging from hemorrhagic erosions to chronic perforating ulcers, which were produced with pilocarpine, epinephrine and morphine, singly and combined, Nakashima²⁶ accepted von Bergmann's theory as the most logical explanation of the pathogenesis of ulcer. Underhill and Freiheit²⁷ made direct observations on the stomach after injecting pilocarpine and epinephrine, from which they concluded that the lesions depended on cyanosis of the stomach and localized areas of anemia, on which the gastric contents exerted

a destructive action. Hayashi²⁸ interpreted the ulcerous changes produced by injecting nicotine into guinea-pigs as due to obstruction of the arteries by muscular contraction. Gallagher²⁹ demonstrated that localized anemia of the duodenal mucosa produced by pressure, if it were maintained for a minimal period of forty minutes, resulted in superficial ulcers. Haeller³⁰ declared that Westphal's results were not due to gastric spasm, but to disturbances of the circulation and metabolism resulting from severe general intoxication. He believed the lesions to be a result of the toxic action of the drug, as he produced ulcerations with morphine, physostigmine and atropine, which exert a different physiologic effect.

Connor,³¹ in a histologic study of peptic ulcers, ascribed the chronicity of ulcer and its failure to heal to thrombosis of the vessels in the surrounding tissue. It is possible that this thrombosis is an effect and not the cause of the local condition, for Mann has reported a thrombotic process from the inflammatory reaction accompanying experimental ulcers. The fact that Morton³² procured healing of ulcers after gastro-enterostomy indicates that the thrombotic element, which would have been unaffected by this surgical procedure, might not have been the essential factor in maintaining chronicity. Konjetzny² did not observe thrombosis in the areas of gastritis and duodenitis, which he regarded as the possible basis of the formation of ulcer.

Anemia.—Many investigators have believed that general anemia as well as local vascular insufficiency has some bearing on the production of ulcer. Quincke first suggested this possibility. Zironi³³ produced ulcerations in 80 per cent of animals rendered anemic by the injection of pyrodine after bilateral vagotomy; in the absence of anemia, lesions appeared in only 59 per cent of cases and were neither so deep nor so extensive. Silbermann,³⁴ Litthauer¹⁶ and Matthes²⁰ presented evidence

to show that anemia and hyperchlorhydria prolonged acute ulcers only to a negligible degree. Turck reported that ulcers occurred in animals simply by keeping them in close confinement until they were debilitated. Gibelli³⁵ reported negative results after anemia produced by bleeding.

Portal Insufficiency.—Finally, interference with the portal circulation, although of indirect action, has been associated with the formation of ulcer. Mueller³⁶ and Fenwick,¹⁸ by sudden occlusion of the portal vein, caused hemorrhages of the mucosa and ulcerations, chiefly in the cardiac end of the stomach. Following ligation of the portal vein, Gundermann³⁷ observed hepatic dysfunction with cerebral, renal and digestive disturbances; hemorrhages and ulcerations occurred in the stomach and duodenum. Payr produced acute ulcers (also certain chronic types) which perforated in three weeks by compression of the portal vein and injections of alcohol and formaldehyde. Turck interrupted the blood supply to the liver and ligated the blood vessels on the lesser curvature of the stomach; this resulted in congestion with hemorrhagic spots and erosions in the stomach. Bollman and Mann³⁸ reported that in a fairly large percentage of dogs subjected to true Eck fistula and fed with coarse kennel food perforating duodenal ulcers may form after a period of several months.

BACTERIAL RELATIONSHIP

As Virchow's theory of the vascular origin of ulcer had initiated considerable study of the influence of that factor, so Cruveilhier's comparison of peptic ulcer to intestinal typhoid ulcer stimulated investigation of the bacteriologic relationship of ulcer.

Early Experiments.—Lebert (1837), probably stimulated by the contemporary advances in bacteriology, injected pus into the veins of animals, with resulting pyemia and erosions of the gastric mucosa. Cohn (1860) produced similar erosions by the same method. The presence of bacteria in the marginal tissues of ulcer was demonstrated first by Böttcher (1874). Greggio and Bolton reviewed the earliest bacteriologic studies as follows: Lettule (1828) produced gastric lesions by the intravenous injection of *Bacillus pyocyaneus*; so also did Charrin and Ruffer. Wurtz and Leudet used lactic bacillus; Rosenbach and

Eshker and Widal and Meslayo, the staphylococcus; Chantmesse and Widal, bacillus of dysentery; Bieulafoy, Bengancon and Griffen, pneumococcus; Saltineano, a coccobacillus and the bacillus of Pfeiffer; Favre, an organism from the blood of a patient with eclampsia, and Rodet and Zaidmann, *Bacillus coli*. The results of these studies were variable, usually with the production of certain gastric erosions.

Ingestion of Bacteria.—Subsequent investigators have adopted two definite methods: the introduction of bacteria by ingestion, or by intravenous injection. Sometimes concomitant procedures were adopted to enhance the action of the bacteria; for example, the production of an artificial anemia. Turck³⁹ produced both acute and chronic ulcers by feeding *Bacillus coli-communis* obtained from the feces of a patient with ulcer to a series of dogs over a long period of time; negative results were observed after the intravenous injection of the same organism. Singer⁴⁰ mixed excreta with the food and observed varying results, but never any lesions comparable to chronic ulcer. Ivy fed cultures of virulent streptococci, and at the same time produced lesions at the pylorus by pinching the mucosa. In five normal dogs the lacerations healed in from five to ten days; in five cachetic animals indurated ulcers occurred in from four to six weeks, and acid was absent in the stomach. He believed that with hypo-acidity swallowed bacteria were implanted in petechial hemorrhages or erosions, and, as a consequence, inflammation and induration of the edges, associated with a defective blood supply, delayed the regeneration of the mucous membrane. Although the general condition improved, chronicity persisted in the ulcer, due, he believed, to the diminished blood supply, the mechanical irritation by coarse foods, the tonic gastric activity and the action of acid pepsin on the devitalized tissue in the base of the ulcer. Rosenow⁴¹ could not demonstrate the formation of ulcer after the oral administration of

H.: The Bacteriology of Ulcer of the Stomach and Duodenum in Man, *J. Infect. Dis.* **17**:219, 1915.

streptococcic strains which produced lesions by intravenous injection, even after the admixture of sharp particles to the diet. Wilensky and Geist⁴² isolated streptococci according to Rosenow's technic, excised a piece of gastric mucosa and injected the organism into the defect at the time of operation. The injection was repeated subsequently when it tended to heal. The characteristics of chronic induration failed to develop in any ulcer and healing was not retarded.

Kotzareff and de Morsier,⁴³ continuing the work of Askanazy⁴⁴ and Kotzareff, injected *Oidium albicans* into local defects in the gastric mucosa of dogs, pigs, guinea-pigs and rabbits. They began their injections twenty-four hours after scraping the mucosa from the lesser curvature and the pylorus, and continued them daily for twenty days. The animals died with acute gastritis, or with perforated or chronic perforating ulcer, and the organism was recovered from the lesion.

Injection of Bacteria.—More definite and constant results have followed the injection of organisms into the blood stream. Steinharter⁴⁵ reported the production of gastric and duodenal ulcers following the intravenous injection of a staphylococcus isolated from an acutely inflamed appendix; the ulcers varied in size from 1 to 7 mm. and were cleanly punched out and circumscribed. Previously, he reported⁴⁶ the production of acute superficial ulcer following the injection of *Bacillus coli-communis* into the vein of an ear of a rabbit; also after the injection of *Staphylococcus pyogenes* into the wall of the stomach with the simultaneous administration of weak acetic acid by mouth. Hoffman⁴⁷ claimed that he isolated a comma-shaped bacillus from the gastric contents in a case of ulcer which, on intraperitoneal injection into a guinea-pig, produced lesions of the stomach and duodenum with duodenitis. The organism was recovered and cultivated, and the lesion was reproduced on second animal passage, thus conforming to Koch's laws.

Hoffman believed it to be a specific organism with selective affinity for the stomach and duodenum. Kobayashi ⁴⁸ tied the cecum of a dog so that the peritoneum would become inflamed, and thus produced ulcers. Saïtta ⁴⁹ associated vagotomy or trauma with the injection of bacteria, but with varying results. Having observed that the injection of diphtheria toxin had produced erosions in the stomach, Rosenau and Anderson ⁵⁰ injected washed diphtheria bacilli into guinea-pigs, with resulting congestion, hemorrhage or ulceration near the pylorus. Hardt ⁵¹ was able to produce lesions following the injection of *Bacillus coli* in only four of eighteen cases (22 per cent), but following the injection of streptococci the ulcer incidence was 57 per cent; seven of these occurred in eight dogs with a Pavlov pouch, many in the pouch itself. This he claimed eliminated the mechanical and acid factors in the production of ulcer.

Specific Streptococci.—Recent studies have been directed toward determining the relationship of streptococci to the formation of ulcer. Ivy injected streptococci into branches of the gastro-epiploic vessels, causing dense fibrinous and fibrous perigastritis, but not ulceration. He concluded that a markedly virulent or specific bacterium is necessary to produce gastric ulceration. Celler and Thalhimer ⁵² recovered a hemolytic streptococcus from gastric ulcers, which, when injected intravenously into rabbits, caused gastric lesions in 13.3 per cent; when this substance was injected into a branch of the gastric artery, lesions were observed in 75 per cent of the cases. *Saccharomyces* and a gram-negative bacillus were also isolated with the streptococcus. From seventeen cases of chronic gastritis or duodenal ulcer, Haden and Bohan ⁵³ isolated a streptococcus which on injection showed gastric and duodenal lesions in 53 per cent of forty-five rabbits. As controls, streptococci from patients not having ulcers were injected into 535 rabbits, and gastric and duodenal lesions resulted in only 7 per cent.

The outstanding contribution on the relationship of streptococci to the formation of ulcer has been Rosenow's work ⁴¹ relating to the elec-

tive localization of streptococci. He postulated that to prove the relationship of a specific strain of streptococcus to ulcer, it is necessary to demonstrate the organism in the ulcer, and to prove by injection that it can reproduce the lesion. He reported histologic studies of a series of ulcers and of their regional lymph nodes, in which streptococci were demonstrated, always most numerous where there was leukocytic infiltration of the subperitoneum. Using dextrose-brain broth, which supplied a gradient of oxygen tension, he cultivated the organisms isolated from ulcers, and from foci of infection in patients with ulcer. His theory is that by sojourn in the body in a focus, these streptococci acquire a specificity by virtue of which they are capable of elective localization in special tissues. To prove this he injected these specific strains of streptococci into rabbits. Hemorrhagic erosions and ulcerations resulted in 61 per cent of rabbits injected with ulcer strains, and in 28 per cent of those injected with strains from foci of the patients with ulcer. The incidence of ulcer was materially reduced by preliminary treatment with vaccine. Careful studies of joints, heart, nerves and other organs showed associated lesions in very low percentages. For a control study he injected nonspecific strains of streptococci into rabbits; gastric hemorrhage resulted in only 20 per cent of cases, and ulcer in only 9 per cent. The specific organisms lodge primarily in the interstitial tissue of the glands; hemorrhage, necrosis and ulceration follow.

Rosenow stated that the lesions resemble ulcers of patients, in situation and in gross and microscopic appearance, tending to become chronic and to perforate and cause fatal hemorrhage. The virulence of the specific strains is low, as death does not follow intraperitoneal injection into mice; nonspecific strains cause a mortality rate of 91 per cent. After cultivation on artificial mediums or after animal passage, the capacity for elective localization is retained only in 30 per cent of cases, and the organisms tend to shift, for example, from the stomach to the appendix or the gallbladder. Rosenow considers these organisms specific because of their apparent constant occurrence in the depths of ulcers of patients, to the exclusion of other organisms, and because they tend to localize in the stomach and duodenum of animals into which injections have been made, a property which is not exhibited by other organisms.

Haden,⁵⁴ Nickel and Hufford⁵⁵ and Nakamura⁵⁶ have done considerable work corroborating Rosenow's results. Using the technic described, Haden studied twelve cases of peptic ulcer from the stand-

56. Nakamura, T.: A Study on Focal Infection and Elective Localization in Ulcer of the Stomach and in Arthritis, *Ann. Surg.* **79**:29, 1924.

point of dental infection. With cultures of streptococci obtained from diseased teeth extracted from patients with ulcer, he produced lesions of the stomach and duodenum in 53 per cent of forty-five rabbits which had received intravenous injections. Nakamura, in studying the dependence of symptoms of ulcer on foci of infection, noted that in nine patients the symptoms (including hemorrhage) were relieved by removal of the foci. In 70 per cent of sixty-six rabbits that received injections of the organisms from these foci, hemorrhagic erosions or ulcers were found near the pylorus; a low percentage of lesions was found in other organs. He emphasized the importance of foci of infection rather than of suture material in causing recurrence of ulcer at the line of anastomosis. Nickel and Hufford found a definite infective focus in all but one of eighty cases of duodenal ulcer; from these they isolated green-producing streptococci which produced lesions in the stomach and duodenum of rabbits when injected intravenously. Moody⁵⁷ studied the pathogenicity of *Streptococcus viridans* recovered from chronic alveolar abscesses in persons with rheumatism, in those with various different systemic disorders and in those perfectly well otherwise. In all the groups the percentage of localization in the stomach was high. He concluded that the lesions produced by organisms from persons without systemic disease are identical with those produced by organisms from persons with systemic disease. He admitted, however, the possibility of well persons later developing systemic disease from such foci. He stated, "There is evidence for and against the property of elective affinity of streptococci, but it cannot be determined wholly by some property inherent in the organism itself." Meisser⁵⁸ produced chronic foci in dogs by devitalizing four cuspids and injecting specific streptococci into the canals. He found hemorrhages or ulcerations or both in the stomach and duodenum of 65 per cent of the series of dogs.

Mention should be made here of the theory of inflammatory ulcer, based on the histologic studies of stomachs that have been resected for ulcer. These studies, although not experimental, have been carried out chiefly by Konjetzny,² Moszkowicz,⁶⁰ Orator,⁶⁰ Lehmann⁶¹ and Puhl.⁶²

62. Puhl, Hugo: Ueber die Bedeutung entzündlicher Prozesse für die Entstehung des Ulcus ventriculi et duodeni, *Virchows Arch. f. path. Anat.* **260**:1, 1926.

Because of the investigation of thousands of resected stomachs, these authors believe that in most cases of gastric or duodenal ulcer there exists gastritis or duodenitis. Puhl reported a series of cases in which the specimens were fixed immediately after removal. Abundant leukocytic infiltration, congestion and edema of the antrum, with ulcerations so numerous as to be called ulcerous gastritis, were found on histologic study. This inflammatory gastritis and duodenitis, with the accompanying superficial erosions, establish, according to this investigator, the necessary initial lesion for the subsequent development of chronic gastric ulcer. He observed gram-positive diplococci in the tissues, but since he was unable to culture them, he did not draw conclusions as to their significance.

TOXIC MANIFESTATIONS

The idea that a local injury to the gastric mucosa acts as the initial cause of ulceration has led to an extensive study of the effects of drugs and physical agents in causing ulceration of the mucosa of the stomach. These have been administered both systematically and locally. Bolton¹⁴ reviewed the work of early investigators who sought to produce lesions by the systemic action of drugs. Overbach rubbed gray ointment into the skin for a period of three months; von Mering injected glycocholate of mercury into cats and dogs; Pillet and Cathetineau used perchloride of mercury; Filhene used arsenious acid. Greggio's review added the work of Virchow and Ebstein, who used phosphorus poisoning; Brouardel and Böhm, who injected arsenious acid subcutaneously; Majer, d'Auitolo and Coen, who caused progressive poisoning of rabbits and dogs with lead acetate; Sarkowsky and Heilborn, who injected corrosive sublimate subcutaneously into rabbits; Ebstein and Peron, who used alcohol; Aufrecht, who used cantharides, and Roy and Poncet, who used ergot and digitalis.

Rehfuss⁶³ studied the effect of the subcutaneous injection of pilocarpine. Injections into guinea-pigs caused ulcer and hemorrhagic erosions in 85 per cent of cases; the effect of the drug was aggravated by the simultaneous administration of atropine. Haden has shown that industrial poisoning, as by benzene (C_6H_6), may cause lesions in the duodenum. Friedman,⁶⁴ by repeated injections of epinephrine for a period of from one to two weeks, produced duodenal ulceration. He also noted that after injections of pilocarpine the preponderance of lesions was in the gastric mucosa. Elliott⁶⁵ caused acute gastric ulcers by

injecting tetrahydro-B-naphthylamine hydrochloride subcutaneously into a guinea-pig. The lesions formed within one or two hours if the stomach was kept filled with food; they were healed and covered with epithelium in three days, the glands regenerating later. Westphal, as has been noted, administered to rabbits large cutaneous doses of pilocarpine, either alone or combined with physostigmine, with resulting ulcers and erosions. He believed that these lesions resulted from vascular spasm due to extreme vagal irritation. In 1917, Murata⁶⁶ repeated these studies with the same results, but he ascribed the local ischemia to obstruction of the supplying artery by a spasmodic contraction of the gastric musculature. In the same year, Hayashi⁶⁷ produced ulcerous changes following the subcutaneous injection of nicotine into guinea-pigs. Later, Hayashi²⁸ caused similar lesions in rats with muscarine; he attributed the result to the elective action of this poison on the stomach by peripheral vagal irritation. The use of morphine, physostigmine, epinephrine and atropine has been mentioned.

Submucous Injection.—The effect of toxic agents when injected directly into the gastric wall has been thoroughly investigated. Greggio in his review stated that Borszéký and Baron produced ulcers by injecting formaldehyde into the gastric mucosa; Rosenbach and Eschker used epinephrine; Serzuki, Payr and Vigliani injected alcohol and chloral; Serzuki used epinephrine, silver nitrate and formaldehyde; Licini,⁶⁸ after injecting apomorphine into the musculature of the stomach, noted hypermotility which changed acute to chronic lesions. Greggio himself produced gastritis with injections of alcohol, but could not induce ulcer to form. Turck sought to produce ulcerous changes by feeding mustard over a period of fourteen months, but with negative results. Ivy produced lesions by injecting 1 cc. of 5 per cent silver nitrate into the submucosa. Friedman and Hamburger⁶⁹ used the same procedure associated with partial pyloric stenosis; hyperacidity resulted, ulcers near the pylorus became chronic, and those in the cardia tended to heal. Acute ulcers, which Dragstedt and Vaughan⁷⁰ observed after injecting silver nitrate, persisted for from three to four months and tended to

become chronic when loops of nonabsorbable suture material were embedded in the gastric walls at the points of injury. Similar ulcers were observed by Hughson⁷¹ to remain active twice as long when associated with delayed emptying of the stomach.

Biologic Toxins.—Of greater interest are those biologic products which exert a toxic action on the gastric mucosa. Ponfick⁷² observed clinical lesions of the stomach and duodenum, following superficial burns, in as short a time as eighteen hours, with associated congestion of the mucous membrane and enlarged lymphoid follicles. Silbermann,³⁴ Vassale and Sacchi⁷³ and Parrascandola caused ulcers in animals following large cutaneous burns, or by injecting the extracts of burned tissues. Greggio quoted Stoknis, Long, Sokoloff and Castel as having caused lesions by glazing the surface of the skin.

Bolton¹⁴ produced what he called a gastrototoxic serum (and an analogous hepatotoxin and enterotoxin) by injecting a suspension of gastric mucosa from a guinea-pig into the peritoneal cavity of a rabbit. After antibodies to this foreign protein had developed sufficient to establish the rabbit's immunity to it, an injection of this immune serum into the peritoneal cavity of a guinea-pig caused death, associated with lesions of the stomach. Injection of this toxin directly into the gastric mucosa also caused ulceration. Bolton found that although ordinarily hydrochloric acid does not exercise any effect on the gastric mucous membrane in concentrations below 0.7 per cent, yet any concentration from 0.25 to 0.7 per cent caused an increase in the size of the lesion produced by injecting gastrototoxic serum, and 0.5 per cent acetic acid (usually innocuous below 2 per cent) increased a lesion produced by the injection of gastrototoxin. Miyagawa, Murai and Terada,⁷⁴ adopting the same method, produced an homologous toxic serum. They immunized one rabbit to the gastric mucosa of another rabbit, and injected the serum of this immune rabbit locally into the gastric mucosa of a third rabbit. The interpretation of the production of these ulcers was that the reabsorption of toxic substances from the necrosed tissue of an ulcer leads to the production in the organism of a cytotoxin which prolongs ulcer and leads to chronicity. Hepatotoxin and enterotoxin, produced similarly

from hepatic and intestinal tissues, were not so certain in their action as gastrotoxin, nor were they specific for a single species.

Latzel⁷⁵ sterilized the gastric juice of a guinea-pig, and by subcutaneous injections into other animals caused anaphylaxis and ulceration of the stomach. Jona⁷⁶ caused similar changes and inhibited pancreatic secretion by subcutaneous doses of extracts of decomposing animal tissues. Greggio, quoting the older workers who used biologic toxins, said that Loepez caused ulcerous changes by injecting a watery maceration of the mucosa or gastric juice of swine; Gundermann³⁷ caused it with extract of liver; Stick, with ptomaines, and Favre, with the blood of a uremic person. In corroboration of the work of Enriquez and Hallion (quoted by Bolton), Rosenau and Anderson⁵⁰ found that diphtheria toxin, when injected into guinea-pigs, caused hemorrhage and necrotic patches in the gastric mucosa. They found lesions in 66 per cent of guinea-pigs used in the production of antitoxin. If, however, the toxin was neutralized by antitoxin, a lesion did not appear. Necropsy revealed congestion, hemorrhage or ulceration at the pyloric extremity, associated with congested suprarenal glands and pleural effusion. Such results were not obtained with tetanus toxin or chemical poisons.

As an extension of his work on the elective localization of streptococci, Rosenow showed that the dead bacteria, or a filtrate of the living culture, possessed the same local affinity as the living organism, causing lesions in the stomach and duodenum. Ivy and Shapiro⁷⁷ injected foreign protein (albumin of egg, beef and cat protein) into the skin of a rabbit until a superficial ulcer formed from local anaphylaxis; this specific protein when later injected into the gastric mucosa caused ulcer to form.

Miscellaneous Methods.—Decker⁷⁸ produced erosions and ulcers by feeding dogs with gruel heated to 50 C. He attributed this not to the scalding but to the congestion of the mucous membrane and the hemor-

rhagic erosions from increased peristalsis. Katzenstein⁷⁹ introduced small, hot, porcelain tubes into the stomach to burn the mucosa; this was followed by injection of phosphoric acid to destroy antipepsin and allow digestion. Ribbert⁸⁰ froze an area, 2 cm. in diameter, of the wall of the stomach with ethyl chloride and methethyl for twelve minutes. The following day a defect appeared in the gastric mucosa, which developed subsequently into an ulcer. Wolfer⁸¹ opened the anterior wall of the stomach, delivered the posterior wall and sutured a lead plate with a small opening to the mucosa. Through this small opening he exposed the mucosa to the roentgen rays and produced a round or oval ulcer with indurated raised margins. One of these ulcers persisted for 585 days. In a later study he noted that if such ulcers were produced close to the pylorus there was a definite delay in the emptying time of the stomach, but if farther away than 5 cm. there was no delay.

Rassers⁸² eliminated all chlorides from the diet of a series of dogs, and administered twelve, eighteen, twenty and twenty-four doses of strong acid pepsin solution over a period of from one to three days. He observed hemorrhagic erosions and small ulcerations in the pyloric antrum and duodenum, which he attributed to the failure of the cells to produce a protective hydroxide against the acid pepsin which was administered.

Kirch and Stahnke,⁸³ observing that in chronic ulcers the muscularis propia is always absent, produced mucosal defects in the stomachs of a series of dogs, and cut away the underlying muscle. From their results they concluded that destruction of the muscle delays healing and is an important factor in the chronicity of lesions, although it does not prevent healing. Morton,⁸² however, noted that healing took place with almost as great ease and rapidity when the muscularis was excised as when the mucosa alone was excised.

Baggio⁸⁴ folded in the anterior wall of the stomach and observed lesions ranging from simple erosions to typical advanced gastric ulcers

on both the introflexion and the posterior wall opposite the introflexion. He attributed these lesions to the traumatic action of the ingesta and the obstruction caused by the introflexion. Slocumb⁸⁵ noted inflammatory changes and multiple ulcers in the duodenum of dogs in which he established partial obstruction of the duodenum by surgical measures.

Ivy noted five ulcers in forty dogs subjected to pylorotomy and gastroduodenostomy. Borszéký⁸⁶ narrowed the pylorus and performed gastro-enterostomy on twelve dogs; he fed them 30 cc. of dilute hydrochloric acid daily. Jejunal ulcers formed only in one of twelve dogs. Dott and Lim⁸⁷ claimed that they observed jejunal ulcers in 90 per cent of the dogs on which they performed pyloric exclusion and gastro-jejunosomy. Montgomery⁸⁸ found chronic jejunal ulcers in four of sixty dogs on which gastro-enterostomy had been performed. Exalto⁸⁹ performed gastro-enterostomy after excluding the pylorus; he then drained the duodenal alkalis of the proximal loop into the cecum. He observed jejunal ulcer, often multiple, in six of ten dogs operated on in this manner.

TROPHIC AND GLANDULAR ULCERS

A different conception of ulcer formation has directed the great volume of work accomplished by the Italian school. They interpret the lesion as of a neurotrophic order, dependent on a defect in the nerve supply to the stomach. Their researches have dealt chiefly with the influence of the vagi, although they have also investigated the central nervous system and splanchnic nerves.

Central Nervous System.—Ebstein⁹⁰ and Brown-Séquard,⁹¹ in the earliest studies on the central nervous system, obtained partial softening, erosion and formation of ulcer in the stomach following circumscribed destruction of the anterior corpora quadrigemina, and after burns of the

cerebral surfaces. Schiff⁹² observed hemorrhagic infiltrations and ulcerations following intersection of the thalamus and cerebral peduncles. Greggio noted mucosal and submucous hemorrhages near the pylorus,⁹³ associated with diffuse gastritis, in half of fifty cases subjected to unilateral and median compression of the cervical cord. He and Bolton cited the production of ulcer by Albertoni, who cut off the cerebral hemisphere; Ewald and Koch, who severed the cervical cord and administered 0.5 per cent hydrochloric acid daily; Schupfer, following bilateral lesions of the anterior and posterior roots of the fifth and eighth dorsal segments; and Quincke and Dättwyler,⁹⁴ who associated lesions of the cord with anemia.

Splanchnic Nerves.—While Durante⁹⁴ was studying the relationship of the splanchnic or sympathetic nerves to ulcerous changes, he repeated the work of Dalla Vedova.⁹⁵ He resected the splanchnic nerves by a lumbar approach, and found that section of the median splanchnic nerve produced circumscribed hemorrhagic or nonhemorrhagic necrosis of the gastric mucosa. The hemorrhagic areas began in the blood vessels of the muscularis mucosae, destroying only the mucosa, and there was evidence of slow regeneration. The nonhemorrhagic type involved the mucosa and submucosa, but did not show signs of regeneration. He considered that the latter type might have resulted from arterial spasm due to the action of epinephrine, because he observed simultaneous intense congestion with signs of hemorrhage in the suprarenal gland on the side of resection. Section of the minor splanchnic nerve caused only occasional lesions, and of the major splanchnic nerve only transient congestion. Since both acute and chronic ulcers occurred, he did not consider that time was an important factor in their formation. Koennecke⁹⁶ observed that excision of the pylorus followed by a Billroth I or a Billroth II operation caused jejunal ulcer in one of five dogs, but bilateral division of the splanchnic nerves following the same procedure caused typical callous deeply penetrating ulcers in all dogs. He attributed this result to removal of an inhibition to secretion.

Celiac Plexus.—Gundelfinger,⁹⁷ after extirpation of the celiac ganglion (by which the action of the sympathetic was removed from the stomach and duodenum, leaving only vagal influence), succeeded in producing gastric lesions. Latzel⁷⁵ reported negative results after extirpation of the celiac plexus. Greggio, in his comprehensive review, reported ulceration of the gastric mucosa and hyperemia in the liver following extirpation of the celiac plexus by Pincus and Samuel, Löwin, Boer and Popielski; others have failed to produce them by this procedure in dogs and rabbits, for example, Adrian, Budge, Lustig, Lamansky and Peiper. Lesions of the plexus were found to produce ulcers and mucous hemorrhages by dalla Vedova,⁹⁵ Kawamura,⁹⁸ and Lilla and Gibelli.³⁵ On the other hand, Donati,⁹⁹ Kobayashi,⁴⁸ Lorenzi¹⁰⁰ and Schmincke¹⁰⁰ observed negative results or only small hemorrhages by irritation of the plexus. Brancati¹⁰⁰ found that ablation of the paravertebral lumbar sympathetic in a dog caused capillary dilatation, necrosis of the mucosa and ulcers at the pyloric region of the stomach and in the adjacent part of the duodenum.

The Vagi.—There has been a much more extensive investigation of the relationship of vagal influence to gastroduodenal lesions. Resection of both vagi in the neck of rabbits was found by Lorenzi to produce hemorrhage in the gastric mucosa fairly frequently. Saitta,⁴⁹ after bilateral vagotomy, observed multiple ulcers when he administered 3 per cent hydrochloric acid by mouth. Finzi¹⁰¹ noted that extirpation of one vagus yielded inconstant results, but that bilateral vagotomy produced, with greater regularity, circulatory disturbances, edema, ecchymosis, necrotic processes and atrophic ulceration. Keppich¹⁰² reported the formation of ulcer in five cases following resection of the vagus. According to Greggio, negative results following vagotomy in the neck of a rabbit are reported by Donati, Kobayashi, Körte and Martini; however, Midulla found that sectioning the vagus in the neck of frogs and

toads caused gastric dilatation, spasm of the pylorus, hypersecretion of the gastric juice, and ulcers which showed a tendency to become chronic and perforate.

The thoracic approach to the vagus has been utilized by others. Zironi,³³ after cutting the vagi around the esophagus of rabbits, observed ulceration in fifty-nine of 100 experiments. Antonini¹⁰³ observed ulcers in only seven of 100 animals after the same procedure; the day following operation there was gastric dilatation and congestion, with the development of lesions possessing the same gross and microscopic appearances as peptic ulcer in man. Cicatrization was not observed. In lesions observed after twenty, twenty-five and fifty days, there was no evidence of healing. Greggio frequently produced hemorrhagic infiltration of the mucosa after bilateral vagotomy, but in only one case did he find a chronic ulcer. This ulcer was 2 cm. in diameter and was situated on the greater curvature. He quoted negative results following this procedure by Krehl, Futsch, Kawamura, Rubaschoff, Muziolli and Fiori, and inconstant results by Samuelson and Contejan.

Thorough studies have been carried out following resection of the vagi in the abdomen. Zironi claimed to have produced gastric ulcer in sixty-four of 100 rabbits following subdiaphragmatic vagotomy. Lorenzi duplicated these observations. Van Yzeren cut both vagi subdiaphragmatically in twenty rabbits; in ten of them he found chronic single ulcers, usually near the pylorus; the earliest was observed in five days and the oldest in 289 days. Ophuls,¹⁰⁴ repeating these studies with the same results, concluded that the lesions were neurotrophic, and that trophic influences are necessary to preserve the normal resistance of the mucous membrane to the digestive action of the gastric juice. Latzel⁷⁵ noted hemorrhagic erosions and ulcerations in ten dogs following subdiaphragmatic vagotomy. Zironi, after similar resection in guinea-pigs, found lesions varying from 0.3 to 1 cm. in diameter in 63 per cent of his studies. Donati⁹⁹ reported negative results after a thorough study by this method. Greggio quoted Gunsburg and Lundi and Kobayashi and Marchetti as having caused diffuse changes in the mucosa or actual ulcers by this procedure; Saitta, Gibelli, Finachiaro, Lilla and Vigliani reported negative results.

Stimulation of the vagus has given contradictory results. Stahnke,¹⁰⁵ in studying the effect of long continued vagal stimulation on gastric

motility and secretion, faradized the vagi for forty minutes. At necropsy gastritis of the mucosa was found in some dogs, and superficial defects in the mucosa were found in others. He considered the ulceration to be a result of increased secretion and chronic gastritis. Keppich,¹⁰² by stimulating the vagi of rabbits with electrodes, produced chronic gastric ulcer in ten of eleven surviving animals. Westphal²⁵ believed that extreme vagal irritation explained the ulcers following the injection of pilocarpine. Hayashi interpreted similarly the lesions produced by muscarine. Gundelfinger was unable to produce ulcers by vagal irritation. Greggio cited Talma and Lichenbeld as having produced lesions by excitation of the vagus; Lorenzi and dalla Vedova, after burns and alcoholic injections into the vagus, caused hemorrhage and ulceration of the stomach. Negative results were reported by Korte and Donati.

The combination of these various procedures has given rather inconsistent results. Donati recorded negative results after abdominal section of the vagi and extirpation of the celiac plexus. According to Greggio, Samuelson noted negative results following the same procedure, with the administration of hydrochloric acid in addition; on the contrary, Lilla found that this surgical procedure alone yielded small punctate hemorrhages of the mucosa. Induced anemia seems to augment these neurotrophic lesions. Zironi increased the incidence of ulcer following thoracic and subdiaphragmatic resection of the vagi from 59 to 80 per cent by inducing artificial anemia; he also claimed to observe an acute ulcer assume chronicity coincident with induced anemia. Greggio caused lesions by vagotomy and the simultaneous administration of alcohol. Vagotomy associated with ligation of the pyloric artery and excision of the mucosa at a corresponding area produced complete healing and cicatrization in three months. Abdominal vagotomy with partial pyloric stenosis gave negative results. By injection of neurine which acts by paralyzing the motor, sensory and secretory terminal fibers to the stomach, Bedarida¹⁰⁶ produced trophic ulcers in the stomach of rabbits. Finally, Auer¹⁰⁷ induced ulcerous changes by removing all the nerve supply of the stomach, which resulted in paralysis, diminished movements and suppressed reflexes. Histologic studies of the terminal nerve endings in ulcers have been made by Perman, Nikolaysen and Askanazy, as reviewed by Okkels.¹⁰⁸ The latter found internal inflammatory

changes of the perineural sheath of nerve branches in the myogastric plexus, nerves embedded in connective tissue and proliferative central cicatrix neuromas. He considered these changes as secondary and non-specific, but believed that they may contribute to the chronicity of ulcers.

The theoretic interpretation of these results is of interest. Greggio concluded that vagotomy alters gastric motility, delays emptying of the chyme into the intestine, causing dilatation of the stomach and possibly interference with the mechanism of the pylorus. Von Bergmann¹⁰⁹ believed that hypertonicity of the vagus produces gastric spasm which puckers the gastric mucosa, strangles it and produces local ischemia and necrosis; this area is digested by the gastric juice and is eroded at its edges, and ulcer develops. Durante⁹⁴ conceived of central psychic stimuli changing the normal vasomotor tonus which might result in rupture of small arterial walls in the stomach, or toxic stimuli which might irritate the peripheral sympathetic system (the trophic nerve controlling the vasomotor nerves of the stomach) and lead to the formation of ulcer.

Glandular Influence.—The effect of glandular activity on the formation of ulcer may be viewed as associated with some type of nervous mechanism. Durante, it will be recalled, noted that ulcers following median splanchnic resections were associated with lesions of the suprarenal glands, and concluded that the effect might have been produced by suprarenal activity.

The studies of numerous investigators have indicated a possible relationship between the glands of internal secretion and the ulcerative lesions of the stomach. There are reported in the literature five cases of ulcer of the duodenum and stomach in man associated with thickening of the suprarenal capsule, hypertrophy, fatty degeneration, congestion and multiple hemorrhages into the glands. Latzel⁷⁵ reported the occurrence of ulcers in three animals following destruction of the suprarenal capsule. Greggio quoted Gibelli, Onde and Cioffi as having produced ulcer by induced suprarenal insufficiency. Mann¹¹⁰ observed acute ulcerations in 90 per cent of animals following the removal of both glands, but none associated with simple removal of the capsules. Hemorrhagic areas were found in the stomach in one animal which died in twenty-four hours; definite ulcers were found in another in twenty-two hours. If the ulcers were situated in the fundus (the pylorus being normal) usually the mucosa alone was involved; if they were in the prepyloric division they penetrated the muscularis mucosae. The duo-

denum was generally injected. The suggested dependence of these lesions on bile and trypsin was ruled out by their continued appearance after the establishment of a biliary and a pancreatic fistula. The acid appeared to be a factor as ulcers did not develop when sodium bicarbonate was fed to dogs on whom suprarenalectomy had been performed. Elliott¹¹¹ noted acute gastric ulcers following the removal of suprarenal glands in cats, and cited it as proof of the full digestive power of the gastric juice. Finzi¹⁰¹ observed edema, congestion, hemorrhage, necrosis and ulceration with an effort to heal following suprarenal suppression. Friedman¹¹² found lesions in the pyloric portion of the stomach to be most frequently associated with removal of the left suprarenal gland, and in the rest of the stomach associated with removal of the right suprarenal gland.

Friedman, while studying the interrelationship with other glands, also noted that removal of one suprarenal gland and one thyroid gland did not have any effect on the integrity of the gastric mucosa, but that intravenous thyroid medication associated with this procedure caused small ulcerations. Finzi also observed that the simultaneous removal of one thyroid gland and one suprarenal gland failed to cause ulcerous changes; he assumed that suprarenal insufficiency can manifest its action on the stomach only with an intact thyroid gland, and that the correlation of internal secretions may have a bearing on the formation of ulcer. Hardt⁵¹ studied the relationship of the feeding of thyroid gland to acidity and found that with increasing thyroid administration there was a decrease in acidity and gastric secretion, while with its interruption there was a return to the normal status. Hayashi, by imitating the so-called mixed stigmatized constitution with the administration of thyroid gland, was able to produce spasmogenic ulcerous changes. Greggio reported ulcers following thyroidectomy as having been produced by Boccardi, Grofredi, Falcone and d'Amore. He reported ulcers following exclusion of the liver by Mueller, Kollicher, Bidder and Schmidt, Beati and others. They have been observed by Bollman and Mann³⁸ following insufficiency of hepatic function induced by partial hepatectomy.

DIGESTIVE JUICES

Thus far, four principal fields of experimentation, vascular, bacterial, toxic and neurologic, have been reviewed. In evaluating the results obtained, one is justified in concluding that the occurrence of ulcer has

111. Elliott, T. R.: Some Results of Excision of the Adrenal Glands, *J. Physiol.* **49**:38, 1914-1915.

112. Friedman, G. A.: The Influence of Removal of the Adrenals and One-Sided Thyroidectomy upon the Gastric and Duodenal Mucosa: The Experimental Production of Lesions, Erosions and Acute Ulcer, *J. M. Research* **32**:287, 1915.

been variable. One investigator has observed results contradictory to those of another; true chronic indurated ulcers have been reported rarely. These studies, however, have answered a part of the problem; they have indicated a variety of means by which an initial acute lesion may be established. Probably only a few investigations (with the exception of Rosenow's work on the elective localization of bacteria) can be interpreted as of direct clinical significance. On the basis of these studies one is still confronted with the problem so aptly stated by Cohnheim in 1880: "The real difficulty in understanding simple ulcer of the stomach is not so much its mode of origin, as the circumstance that it usually so obstinately refuses to heal." He continued, referring to ulcers of embolic origin: "There must be in addition an unknown something which prevents the healing of ulcer. But whether, as has more than once been suggested, this something consists in an abnormal acidity of the gastric juice, we have as yet no positive investigation to show." Mann and his co-workers¹¹³ have probably supplied this desideratum. By "positive investigations" considerable evidence now indicates that the "unknown something" consists in the action of mechanical factors and the disturbance of the factors of acid and alkali at the pylorus. The mechanical factors and disturbance of the optimal chemical conditions for each side of the pylorus, which result from the surgical procedures employed in these studies, are probably the sole etiologic factors in causing the experimental ulcers, and possibly form the basis for the chronicity of clinical ulcers, determining their inability to heal.

Chemical Methods.—The importance of the digestive juices in relation to ulcer has long been suspected, and many investigations have been directed toward evaluating their influence. Saitta⁴⁹ administered 3 per cent hydrochloric acid by mouth following vagotomy and found multiple ulcers, whereas without the giving of acid he observed only hemorrhagic erosions. Friedman found that ulcers in the pyloric region, caused by the submucous injection of silver nitrate, became chronic when associated with hyperacidity produced by pyloric stenosis. Litthauer¹⁶ produced ulcer by administering 200 Gm. of hydrochloric acid to a dog, after ligation of gastric vessels and excision of a corresponding piece of mucosa. He also produced ulcers by feeding acid after having caused

anemia by injection of pyrogallac acid. Gibelli¹¹⁴ failed to produce ulcers by simply administering acid by mouth. Bolton,¹¹⁴ as was noted under toxic manifestations, found that hydrochloric acid did not have any effect on the gastric mucosa under a concentration of 0.7 per cent, but that after a local lesion had been produced by the injection of gastrototoxin, concentrations as low as 0.25 per cent caused an increase in the size of the lesion. Acetic acid below a concentration of 2 per cent is innocuous, yet with the lesion once established by gastrototoxin a 0.5 per cent solution increased its size. Hydrochloric acid, the only digestive juice capable of attacking connective tissue, caused necrosis of granulation tissue in the base of the ulcer, and delayed healing of the ulcer. Bolton also delayed healing of ulcers in the rabbit by artificial hyperacidity, but he discounted the acid factor because he found that ulcers did not heal any slower with a high Pavlov pouch and acid stasis than with a low pouch and free drainage. Butsch¹¹⁵ claimed that acidity has some bearing on the formation of ulcer because of a higher occurrence in the Roux Y-anastomosis, in which the alkaline neutralizing factor is diminished. He also called attention to the fact that ulcer is rarely seen after anastomosis for carcinoma of the stomach, associated with diminished, or the absence of, acidity. Durante claimed that an excess of acid caused irritation and gastritis, epithelial desquamation, enlargement of the follicles and ultimately rupture and ulceration.

Smith¹¹⁶ studied the relationship of bile to ulceration of the gastric mucosa. He applied a mixture of bile and acid to the mucosa of the stomach, without effect. An interrupted application, however, first of bile alone, then immediately afterward of 0.5 per cent hydrochloric acid, caused a greenish-yellow pedicle and a precipitate from the mucus, with occasionally an underlying area of necrosed epithelium. The following day superficial necrosis of two-thirds the depth of the mucosa with leukocytic infiltration had occurred. Injection of bile and acid into the lumen of the stomach by a stomach tube or through the pylorus, during the period of digestion, caused excoriation, hemorrhagic infiltration and ulceration. He observed negative results in a stomach during fasting. After tying the esophagus and duodenum, he injected bile into the stomach for twenty-four hours; large quantities of bile alone caused hemorrhagic lesions; small amounts of bile with acid also caused lesions;

bile injected with a 5 per cent solution of sodium bicarbonate did not produce lesions except in one instance. He concluded that the presence of acid is necessary for the injury of the mucosa by bile. He quoted Rywosch as having produced inflammation and gangrene of the stomach of rabbits by feeding an excess of bile salt. Oddi and Dastre¹¹⁷ did not get these results following cholecystogastrostomy. Smith concluded that it must be conjectured whether in man the bile may become a source of injury to the epithelium, particularly since it normally regurgitates through the pylorus into the stomach. Sellards¹¹⁸ studied the effects of bile salts by injecting sodium glycocholate intraperitoneally. He produced large hemorrhagic areas in the stomach and ulceration of the mucosa. The subcutaneous injection of bile or bile salts produced similar lesions. Small repeated doses tended to localize ulcers near the pylorus. Since there were only a few minute lesions in the lungs and intestines, Sellards claimed for the bile salts a specific action on the gastric mucosa.

Such methods of studying the influence of the digestive juices are limited both in variety of experimental procedures and in the lack of control of physiologic reactions. Recourse must be had to surgical methods in order to determine the nature of the physiologic interrelationship of the juices. It is true that unphysiologic conditions may be established by such surgical measures, but as hepatectomy makes it possible to study the function of the liver and pancreatectomy to study the function of the pancreas, so the surgical procedures which have resulted in the formation of ulcer disturb the normal status (as nature may do with greater finesse), and produce effects which make it possible to analyze the significance of the juices from the point of view of formation of the ulcer.

Surgical Methods.—Kapsinow¹¹⁹ excluded the bile from the digestive tract by implanting the fundus of the gallbladder into the pelvis of the right kidney (cholecystonephrostomy). When healing was complete he ligated and divided the common duct. The animals lost weight and refused food, and tarry stools developed. Necropsy was performed in two or more weeks. In seventeen of forty-three animals single or multiple ulcers from 2.5 to 5 cm. in diameter, with punched-out overhanging edges were formed. They extended to or perforated the serosa. Kapsinow quoted Whipple as having produced ulcer after ligating the

common duct in the presence of a biliary fistula, but he criticized the work because of the possibility of infection ascending through the fistulous tract. Gundermann,³⁷ after simple ligation of the common duct, observed the same symptoms of hepatic dysfunction as after partial ligation of the portal vein, namely, cerebral, renal and gastroduodenal disturbances, the stomach and duodenum showing hemorrhages and ulcerations. Smith anastomosed the gallbladder to the stomach with and without ligation of the common duct, but results were negative in both instances. He reported negative results after the same procedure by Oddi and Dastre. Beaver,¹²⁰ likewise, did not observe ulcers following cholecystogastrostomy and ligation of the common duct. As stated, Greggio quoted Mueller, Köllicher, Bidder and Schmidt, Beati and others as having noted ulcers after exclusion of the liver. Bollman and Mann³⁸ reported that ulcers had perforated following partial hepatectomy, true Eck fistula and ligation of the common duct, procedures which probably influenced the quantity of bile entering the duodenum.

Little study has been made of the effect of excluding the pancreatic juice alone. Jona,⁷⁶ after tying the pancreatic duct in eleven animals, found ulcers of the duodenum, stomach and jejunum which he ascribed to lack of neutralization of the acid chyme. Gallagher²⁹ observed delayed healing of traumatic ulcers of the duodenum after ligation of the pancreatic duct.

The combined elimination of the bile and pancreatic juice has been studied thoroughly. Kehrer¹²¹ implanted the pancreatic duct into the appendix or lower part of the ileum and anastomosed the gallbladder to the same site, ligating the common duct. In six animals that died at different intervals, he found marked injury to the wall of the stomach. Necropsy after thirteen, twenty-five and sixty-four days disclosed superficial circumscribed necrosis with deeper necrosis in three other dogs on which necropsy had been carried out after nine, twenty-five and 100 days. Macroscopically and microscopically, they were typical ulcers. Mann and Williamson¹²² studied the production of ulcer in the duodenum, following transplantation of both the bile and the pancreatic ducts into the lower part of the ileum. The ulcers produced were single and multiple, indurated, varying from 1 to 3 cm., and were situated in the region between the pylorus and the ampulla of Vater.

Mann was the first to study the formation of ulcer following the entire elimination of all the duodenal alkaline juices. The historic development of his ideas show clearly the underlying factors in these studies.

122. Mann, F. C., and Williamson, C. S.: The Experimental Production of Peptic Ulcer, *Ann. Surg.* **77**:409, 1922.

While investigating the problem of whether or not the duodenum produced a secretion essential to life, he devised a one-stage operation, excising the duodenum, anastomosing the jejunum to the transected pylorus and then implanting the pancreatic and bile ducts into the anastomosed jejunum. In two of ten dogs operated on, peptic ulcer resulted. Mann and Williamson then transplanted the bile and pancreatic ducts into the ileum, from 30 to 50 cm. from the cecum. Definite ulcers developed in ten of thirty-one animals (five ulcers were chronic). Removal of the duodenum and anastomosis of the jejunum to the pylorus, with transplantation of the bile and pancreatic ducts into the distal part of the ileum, resulted in ulcers in eight of the ten dogs operated on. The procedure was then simplified by devising the "duodenal drainage" operation. By this method the duodenum was isolated by transection at the pylorus and at the upper part of the jejunum. The pyloric end of the duodenum was closed in and the distal end anastomosed to the distal part of the ileum; the free end of the jejunum was anastomosed to the pylorus. With the duodenal alkaline juices drained into the ileum, the acid chyme of the stomach drained into an unprotected jejunum. Definite ulcers developed in fourteen of sixteen animals. They were usually situated a few millimeters from the gastrojejunal anastomosis. They developed usually within one or two months after operation, were from 4 to 15 mm. in diameter and penetrated to various depths. A gray covering first appeared over an area on the mucosa where killed, coagulated cells were present. Hemorrhage occurred between the adjacent tubules. As the mucosa disappeared, leukocytic infiltration developed, and the process penetrated the muscularis mucosae. Perforation occurred in from forty-eight to sixty hours, chronicity was established in three weeks, or the lesion was the same at the end of five months as at the end of one month.

In evaluating the factors involved in this result, Mann conceived of the acid chyme as being ejected through the pylorus by the gastric contractions, as if through a nozzle, and impinging forcibly against the wall of a segment of intestine containing little, if any, alkali; the mechanical and chemical action of this stream led to necrosis of the epithelium and the formation of ulcer.

The degree of acidity and the amount of acid to which the ulcer-bearing area is subjected depends normally on the balance at the pylorus between the gastric acid chyme and the alkaline secretions of the duodenum. The combined intestinal, pancreatic and biliary secretions must be sufficient to neutralize the acid chyme passing the pylorus to from 0.12 to 0.14 per cent, as shown by Boldyreff.¹²³ Mann showed that if,

123. Boldyreff, W.: The Self-Regulation of the Acidity of the Gastric Contents and the Real Acidity of the Gastric Juice, *Quart. J. Exper. Physiol.* 8:1, 1915.

after a duodenal drainage operation, the duodenal juices were drained back into the jejunum just distal to the gastrojejunal anastomosis, so that such neutralization did occur in the ulcer-bearing region, a lesion did not develop. Morton similarly showed that secondary anastomosis of the closed duodenum to the jejunum after surgical duodenal drainage, so that alkalis drained back at the site of ulcer, led to the healing of an existing ulcer.

By several experimental methods, Morton¹²⁴ further confirmed the idea that the chemical and traumatic factors are of major importance in establishing chronicity in ulcers and failure to heal. He excised pieces of mucosa from the lesser curvature in dogs after the duodenal drainage operation, and showed persistence of the defect in from 50 to 62 per cent of those in the antrum after a period of two weeks. This was in contrast with normal controls, in which similar areas with excised mucosa healed in two weeks, with complete epithelization. Incidentally, after excision of mucosa from the greater curvature of the antrum in drainage operations healing was more rapid, showing that whatever the factors that prevented healing, they were more active on the lesser curvature. Finally, Morton transplanted jejunal patches with an intact circulation into several different areas in the gastric wall of dogs on which duodenal drainage had been performed. In thirteen cases, four ulcers developed on the patches. Again suggesting the greater activity of the destructive forces on the lesser curvature, three of these ulcers developed in patches on the lesser curvature, and only one on a patch elsewhere. This is in contrast with Morton's control studies (and corroborating earlier work by de Takats and Mann¹²⁵), in which only one ulcer developed in jejunal patches on the lesser curvature and none on patches in other parts of the stomach in a series of normal dogs. The observations extended over a period of from thirty-six to 419 days.

Mann considered the active mechanical factor in the duodenum to be the force of the impinging stream ejected through the pylorus. In the stomach, Morton considered the mechanical factors chiefly active in localizing the ulcers as the paucity of protecting rugae in the prepyloric segment, particularly along the "Magenstrasse" with its poor blood supply, and the convergence of the lines of force along the lesser curvature, as suggested by Aschoff.¹²⁶

I. EFFECTS PRODUCED BY DRAINAGE OF THE DUODENAL SECRETIONS BACK INTO THE STOMACH: MECHANICAL FACTORS

The following report represents my work on peptic ulcer produced experimentally by the methods devised by Mann. The principle of the methods used by Mann and his co-workers consists essentially in shunting the alkaline secretions of the duodenum away from the pylorus so that the gastric juice and chyme are not neutralized. This has been accomplished by operations such as transplantation of the bile and pancreatic ducts into the distal part of the ileum, or by Mann's method of surgical duodenal drainage.

As stated in the preceding review, Mann and Williamson demonstrated the occurrence of ulcer in the duodenum in about 50 per cent of the dogs in which the bile and pancreatic ducts had been transplanted into the distal part of the ileum. Morton showed that, following surgical duodenal drainage, peptic ulcers formed in the anastomosed jejunum in approximately 100 per cent of experiments. He also found that, whereas in the normal dog traumatic lesions of the gastric mucosa healed readily, following a duodenal drainage operation such lesions tended to become chronic peptic ulcers. In a similar way he demonstrated a greater tendency toward ulceration of transplants of jejunal patches in the gastric wall in dogs subjected to duodenal drainage than was the case in normal dogs.

METHODS

In the present study the operation of surgical duodenal drainage was modified in such a way that while eliminating the alkaline secretions from the distal side of the pylorus they were shunted to the gastric side. This was accomplished by draining the duodenal secretions into the fundic portion of the stomach rather than into the distal part of the ileum. It was an apparent assumption that these alkalis might control the acid factors in the stomach and thus prevent the formation of the ulcers which developed after total elimination of the alkalis.

• The same type of dogs used in the former studies were used in these experiments. All surgical procedures were carried out with the dogs under ether narcosis. Careful aseptic technic was observed throughout. Clamps were not used at the lines of anastomosis. Absorbable catgut was used for all intestinal suture work.

The abdomen was opened by a high median line incision. The pylorus was exposed and the vessels and nerves to the upper border were cut between two ligatures. The pylorus was severed, and the duodenal end was inverted. In like manner, the jejunum was severed just distal to the ligament of Treitz. The distal end was brought up and anastomosed to the open gastric end of the pylorus, thus reestablishing the continuity of the tract, with the duodenum excluded. The distal end of this isolated duodenum was anastomosed to the fundic portion of the stomach. This was done by *end-to-side anastomosis*, or by *side-to-side anastomosis* following closure of the distal end. These anastomoses were made on either the anterior or the posterior surface of the stomach. The type of anastomosis employed did not have any influence on the end-results of the experiment (fig. 1).

The modified technic of surgical duodenal drainage established a new type of disturbance of the relationship between the gastric chyme and the duodenal juices. The whole volume of duodenal alkalis, during their entire secretory cycle, was shifted from the distal side of the pylorus into the fundic portion of the stomach. These duodenal secretions were now retained in the upper part of the digestive tract, were freely intermixed with the gastric juice, and in this state passed through the pylorus into the jejunum (now unprotected by alkalis) and on into the intestinal tract (fig. 2). The significant question was: Could these alkalis which emptied into the stomach control the acidity of the gastric juice and thus prevent the formation of ulcers?

After operation, food was withheld for from two to three days. The dogs recovered quickly from the effects of the operation and were placed on routine kennel care. They were fed regularly with kennel food, and supplementary feedings of milk and syrup were given if they lost weight.

Fig. 1.—Operative procedure, showing the duodenum draining the secretions of the gallbladder, liver and pancreas into the fundic portion of the stomach.

RESULTS

Types of Ulcer.—Following the operation typical ulcers of the jejunum, such as were reported in all the earlier studies by Mann and his colleagues, formed in approximately 80 per cent of a series of twenty-six dogs. This figure is slightly lower than in the other series, which can be accounted for by the fact that two dogs were etherized because an ulcer was suspected; at necropsy, an ulcer was not found. Two other dogs in this series are still living two years after the operation, and the presumption is that ulcers have not developed. These four dogs have lowered the percentage of occurrence of ulcer.

The ulcers usually formed within from one to three months. Some of them perforated, causing sudden death. Others were first suspected when the dogs began to refuse food and lose weight. If the dogs were etherized at this time, ulcers of the anastomosed jejunum were usually found. The variations in the length of time in which the ulcers formed

preclude the possibility that operative trauma, thrombosis of vessels or cachexia are the essential factors concerned in producing these lesions.

Usually single, but sometimes multiple, ulcers were found. They were situated just beyond the suture line, and were usually regressive up to the gastric mucosa. If they were multiple they were distributed over an area of from 5 to 7.5 cm. of the upper part of the jejunum. The acute ulcers were cleanly punched out, suggesting a rapidly progressing type of lesion. The three layers of the intestinal wall, the

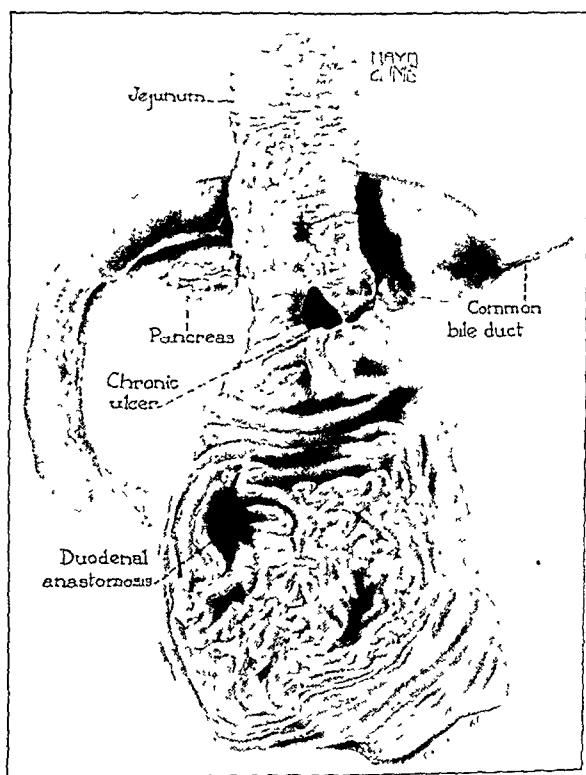

Fig. 2.—Anastomosis of the distal end of the duodenum to the fundic portion of stomach, thus draining the alkalis into this segment. The gastric chyme with the duodenal alkalis intermixed empty into the unprotected jejunum. A chronic ulcer appears at the usual site of formation.

mucosa, muscularis and serosa, were all extensively involved. Even these ulcers were not truly acute, in that the edges of the lesion were slightly indurated, suggesting some of the tissue reaction responsible for chronicity in other specimens (fig. 3).

The subacute ulcer, which was the type most frequently seen, gave definite evidence of early chronicity. The edges of the crater were thickened, due to the round cell infiltration from the tissue reaction.

There was graded involvement of the three coats in a terraced manner. The mucosa was ulcerated most extensively, its edges indurated, rounded and overhanging. The muscularis was eroded less widely, and the serosa least of all. The occurrence of ulcers, without contact at the suture line,

Fig. 3.—Acute ulcer of the jejunum following surgical duodenal drainage. Encroachment on line of anastomosis, with gastric mucosa intact.

indicates that the ones which encroach on the suture line are regressive (fig. 4).

The chronic indurated ulcers possessed all the characteristics of the crater type of ulcer observed in man. They were of considerable depth,

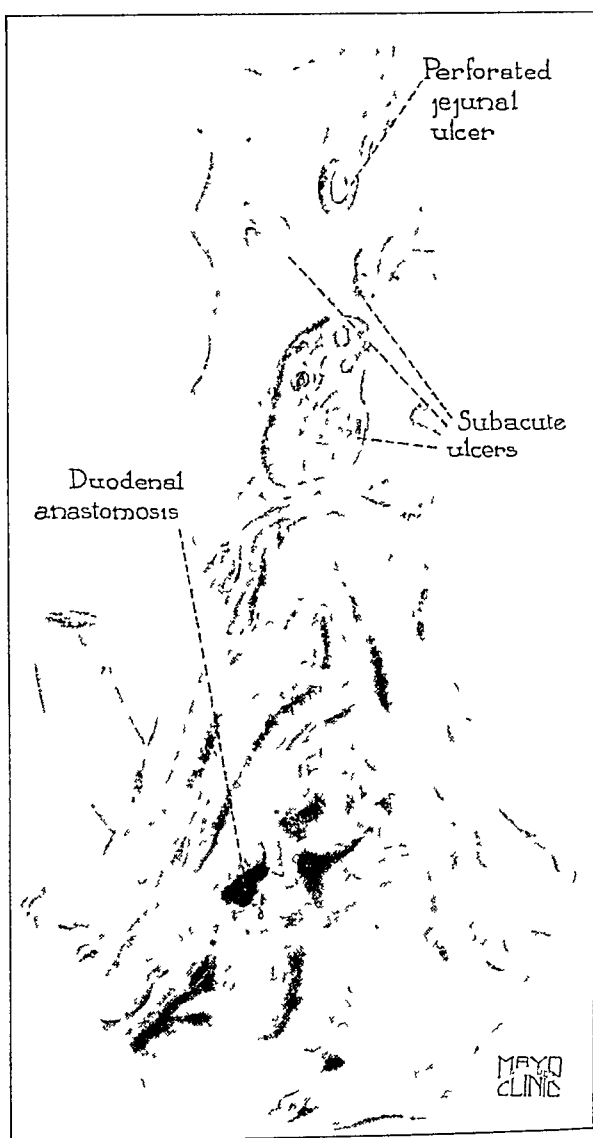

Fig 4—Subacute types of ulcer with less extensive ulceration of underlying muscularis and serosa than of the mucosa. Ulcers at considerable distance from line of anastomosis

from 6 to 10 mm., with sloping indurated walls. The mucosa was thickened and overhung the sloping walls. The base of these chronic ulcers was usually formed by the peritoneal surface of an adjacent organ, such as the liver, onto which they had slowly perforated. This slow perforation afforded the tissues an opportunity to establish a more intense reaction which is characteristic of chronicity, that is, round cell infiltration and fibrosis (fig. 5).

Mechanical Factors.—The basis for the production of these experimental ulcers has been attributed mainly to the mechanical and chemical factors involved in the physiologic functions of this region. Two of the specimens in this series presented significant evidence of the influence of

Fig. 5.—Typical chronic indurated crater type of ulcer. Small perforation in base of ulcer was penetrating onto lobe of liver, which saved the animal from death by perforation.

the two mechanical factors involved: the force of the stream ejected through the pylorus and the friction of coarse cellulose foods.

In the first specimen, a chronic peptic ulcer about 6 mm. in depth was present; fifty or more hairs from the dog's hide were embedded in the sloping wall of the distal half of the crater. There were only one or two hairs in the proximal half of the ulcer. Apparently, the chyme was ejected through the pylorus and impinged on this segment of the intestine with force sufficient to embed the hairs in the wall of the ulcer. This, of course, is not controlled proof, but it is suggestive evidence of the mechanical factor established by the passage of chyme from the stomach (fig. 6).

The other mechanical factor, the destructive friction of coarse cellulose foods on the delicate granulations and epithelial cells of a heal-

ing ulcer, was strikingly illustrated by the second specimen. The dog died suddenly from a perforated ulcer. At necropsy the peritoneal cavity did not show gross peritonitis. In the jejunum, just distal to the suture line, was a perforated ulcer through which protruded about 0.3 cm. of the tip of a moderate-sized pyramidal piece of turnip, a constituent of the mash fed to the dogs. The jejunum was carefully opened so as to leave the piece of turnip undisturbed. The lumen of the bowel and stomach contained a considerable quantity of bloody fluid, all of which was retained within the lumen of the viscera, because the ulcer had

Fig. 6—*a*, absence of hairs in proximal end of ulcers; *b*, hairs embedded in the distal half of the crater of the ulcer

been completely occluded by the turnip which had perforated it. This perforation of an ulcer represents a most extreme degree of destruction by the friction of food (figs. 7 and 8).

COMMENT

In the early studies by Mann and his colleagues in which the original method of surgical duodenal drainage had been used, ulcers were produced by entirely eliminating the alkalis from the pyloric region and exposing the segment beyond the pylorus to the full autolytic action of

the gastric chyme. In the present studies the alkalis are still retained in the upper part of the intestinal tract but proximal to the pylorus; this allowed the uncontrolled autolytic action of the gastric chyme to persist beyond the pylorus. The resulting lesions indicated that one rôle of the alkalis, in the normal physiologic relationship, is to prevent the

Fig. 7.—Piece of turnip perforating an ulcer, just distal to the pylorus; other pieces of turnip were free in the cavity of the stomach.

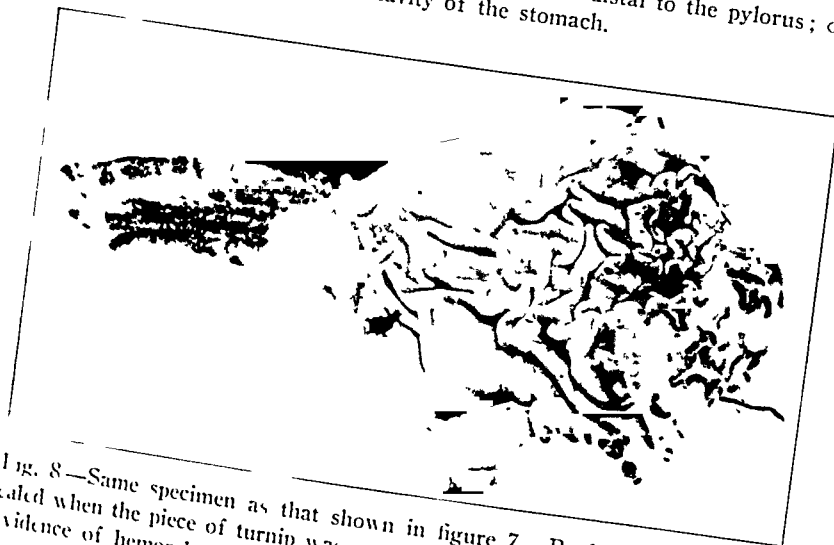

Fig. 8.—Same specimen as that shown in figure 7. Perforated type of ulcer revealed when the piece of turnip was removed. Discoloration of the bowel points to evidence of hemorrhage.

formation of ulcer, not by any specific protective action, but by some type of buffer or diluting action beyond the pylorus that terminates the acid peptic activity of the gastric chyme.

The results of these experiments emphasize the importance of the mechanical factors in causing chronic peptic ulcers. The specimen in

which the hairs from the dog's hide were found embedded in the distal half of the ulcer constitutes an observation just as suggestive as if particles of carbon had been mixed with the dog's food and these had been observed in the wall of the ulcer. The specimen indicates the force with which the stream ejected through the pylorus impinges on the site of ulcer formation.

The destructive action of coarse cellulose food is apparent when the delicate mechanism involved in the healing of an ulcer is considered. Morton, summarizing the experimental work done on the healing of ulcer, stated that Mann observed:

The base of the lesion is first cleaned, the slough separates, and a protecting coat of serum and coagulum forms over healthy granulations. These processes ordinarily take about four days. Simultaneously the mucosa begins to grow out from the edges as a thin layer of flat epithelial cells. The edges of the mucosa tend to overhang and the granulations to push up in the center, so that the growing edge of mucosa is protected in the resulting depression. This initial stage which has the effect of also decreasing the area to be healed over takes place in about ten days. Once initiated, the healing, if undisturbed, is rapid. In twenty days three-fourths or more of the base is covered with epithelium, and in thirty days the lesion is usually healed entirely. The scarring is in many cases hardly noticeable.

How easily this delicate mechanism might be compromised by the influence of friction was suggested by the piece of turnip which had perforated an ulcer. If a large piece of cellulose food could exert so destructive an influence, it is reasonable to assume that cellulose food of varying degrees of coarseness would exert a graded amount of friction, thus continually aborting the reparative tendencies of an ulcer.

That the assumption is justified is borne out by the experience of Bollman and Mann with dogs on whom an Eck fistula had been made. In a considerable percentage of the dog's acute perforated ulcers of the duodenum developed while they were fed on coarse food which contained much cellulose material. When the coarse foods were replaced by a soft or liquid diet, the occurrence of ulcers was decreased. This observation affords control evidence that with a partial deficiency (qualitative or quantitative) of the bile in the duodenum, the presence or absence of coarse cellulose food was the important factor in determining the frequency of the formation of ulcers in the duodenum.

On the gastric side of the pylorus there are two factors which would augment the friction of coarse cellulose food in the prepyloric segment, and thus greatly influence the localization of ulcers in this segment, as occurs clinically, and as reported in Morton's experiments. The first factor, as Morton pointed out, is the anatomic arrangement of the mucosa in this segment, which is closely attached and does not form protective rugae such as are found in the fundic portion of the stomach. This is particularly true of the lesser curvature. It is interesting to note

that there is total absence of such rugae in the duodenum and jejunum, which are most subject to ulceration and would thus permit maximal friction by coarse cellulose food.

The second and probably a highly important factor in augmenting the friction of cellulose food in the stomach is the type of motor activity in the prepyloric segment which I observed while working with the test meal of meat. In response to this adequate stimulus, the whole prepyloric segment was thrown into vigorous tonic contraction, so that it appeared sausage-shaped. Frequent peristaltic waves traversed the segment during early digestion, being superimposed on this tonic contraction. In contrast to this activity, the fundus appeared like a big motionless ball, with a simple wavering around its periphery. Pieces of cellulose food caught between the approximated, vigorously contracting walls of the prepyloric segment might exert considerable destructive friction on the reparative granulations and epithelial cells of an ulcer. If these particles were rejected at the pylorus and driven back into the fundus, as indicated by Cannon's study, the friction of each particle might be multiplied many times.

SUMMARY OF STUDY I

In this study, the technic of surgical duodenal drainage was so modified that the alkaline secretions of the duodenum were shunted from the distal side of the pylorus into the fundic portion of the stomach. Despite the volume of alkalis drained into the stomach, ulcers still formed in the anastomosed jejunum in approximately 80 per cent of the experiments.

Evidence was obtained which substantiated Mann's interpretation of the important mechanical factors that are active in causing these experimental ulcers, and which probably influence the localization of clinical ulcers. On the duodenal side of the pylorus these are the result of the force of the impinging stream ejected through the pylorus, and of the destructive friction of coarse cellulose foods on the reparative granulations and epithelial cells of a healing ulcer. On the gastric side of the pylorus there is the same friction of coarse cellulose food augmented in the prepyloric segment by the absence of protective rugae, particularly on the lesser curvature, and by the vigorous tonic and peristaltic contractions of this segment which appear in response to an adequate meal.

II. THE CHEMICAL FACTORS IN EXPERIMENTALLY PRODUCED PEPTIC ULCER

The present study was an investigation of the chemical factors involved in the development of the peptic ulcers produced by the experimental procedures devised by Mann. Former experiments have indicated fairly definitely the mechanical factors which influence the

development and localization of the ulcers. The active chemical factors have been suggested by the nature of the disturbed physiologic function. The rationale of the methods is best indicated by Mann's own words:

Our results in a preliminary series of experiments in which acid was administered orally, as well as the results of previous investigators, demonstrated that simulating the so-called "hyperacidity" and "hypersecretion" by the artificial administration of acid would be very difficult. The upper part of the intestinal tract can be subjected to an acid medium just as effectually by injuring the alkali-producing mechanism as by the administration of acid. We, therefore, undertook to eliminate singly and in combination, the various constituents of this mechanism, and it was found that injury of any one of these constituents caused the development of typical chronic peptic ulcer in a small percentage of experiments. We finally devised a method which consisted essentially in draining the alkaline secretion which is poured into the duodenum, into the ileum at a considerable distance from the point of emergence of the acid from the stomach into the intestine. Following this procedure, a typical peptic ulcer developed in a high percentage of experiments.

These ulcers, he thought, resulted from a disturbance of the normal relationship between the gastric and duodenal juices beyond the pylorus, besides the mechanical factors of that region.

The nature of this disturbed relationship between the gastric and the duodenal juices has never been exactly determined. Mann showed that an acid reaction to litmus persisted far down the intestinal tract following surgical duodenal drainage, whereas normally the reaction is alkaline to litmus. This was the basis of his idea that the acid chyme which passed the pylorus was not neutralized and acted as a major factor in the development of these ulcers.

Two hypotheses suggest themselves as to the nature of the disturbed relationship of the secretions resulting from this procedure. First, if Boldyreff's theory is accepted that the acidity of the gastric juice is regulated by regurgitation of duodenal alkalis into the stomach, then these procedures would injure this mechanism so that the mucosa would be exposed constantly to highly concentrated acid. This persistent state of hyperacidity might account for the production of the ulcers. If this theory is not true and the acidity of the gastric contents is independent of regurgitation of the duodenal alkalis, then the second hypothesis is probable, namely, that the acid peptic activity of normal gastric chyme causes these ulcers, because its action is not terminated beyond the pylorus following the loss of diluting or buffer secretions, bile and pancreatic juice. It is important to know which hypothesis is true, because, if it is the second one, these experiments have demonstrated the highly destructive action of the normal gastric chyme under experimental conditions which allow it to ulcerate the mucosa.

METHOD

By a method of fractional gastric analysis that I devised¹²⁷ for use on the normal dog it is possible to measure the effect of these procedures on the chemical changes of the gastric contents during digestive activity and during rest. This method, which I shall report in more detail elsewhere, consists in feeding a fasted animal with a meal of meat and water. Half an hour after feeding, single specimens are aspirated every thirty minutes until free acid appears. Then the aspirations are made every fifteen minutes until the free acid is neutralized. Chemical determinations are made for total and free acids, and these are charted. The total chlorides are titrated, and the chlorine value of the free acid deducted, so that the resulting figure, which is charted, indicates the chlorine value in neutral or combined form.

Three groups of dogs were operated on so as to repeat the methods used in the whole series of studies by Mann and his colleagues. Studies with the fractional

Fig. 9.—Three types of operative procedures: modified surgical duodenal drainage with section in first portion of duodenum; surgical duodenal drainage with section at pylorus; surgical drainage of duodenal alkalis into fundic portion of the stomach.

test meal of meat were made before and after the operations. The three procedures were as follows (fig. 9):

1. *Modified Surgical Duodenal Drainage.*—The usual type of drainage operation was modified by sectioning the first portion of the duodenum at the middle, rather than sectioning the pylorus. The duodenojejunal flexure was sectioned beyond the ligament of Treitz. The proximal end of the duodenum was closed in, and the distal end was anastomosed to the distal part of the ileum. Duodenojejunal anastomosis was made beyond the pylorus after the lumen of each segment had been enlarged by a longitudinal incision, thus obviating any mechanical dysfunction from stenosis at the line of anastomosis. Furthermore, nerves or significant blood vessels were not severed in the procedure.

127. McCann, J. C.: Unpublished data.

2. *Surgical Duodenal Drainage*.—The original method was used for this group. The nerves and vessels to the upper border of the duodenum were cut between ligatures. The pylorus itself was severed and the usual anastomoses made: the jejunum to the pylorus, and the closed duodenum to the distal part of the ileum. Thus all the disturbances of motor function present in the early studies as a result of the manipulations at the pylorus were present in this group.

3. *Surgical Duodenal Drainage Back into the Stomach*.—The technic was the same as that reported in the preceding study. The pylorus was severed and the duodenal end inverted. The duodenojejunal flexure was severed just distal to the ligament of Treitz. The distal end of the jejunum was anastomosed to the open gastric end of the pylorus. The distal end of the isolated duodenum was anastomosed to the fundic portion of the stomach. Thus the whole volume of duodenal alkalis was shifted from the distal side of the pylorus into the fundic portion of the stomach.

RESULTS

In the first procedure, since the duodenum rather than the pylorus was severed, all impediments to normal emptying were avoided. As

Fig. 10.—Chronic ulcer; the same essential character of curves occurred in response to a test meal before and after the surgical drainage of the duodenal alkalis from the pylorus into the distal part of the ileum; anastomosis in the middle of the first portion of the duodenum. In this and the following charts, the solid line with the hollow circles indicates the free hydrochloric acid; the solid line with the solid circles, the total acid, and the broken line with the solid circles, the combined chlorine.

shown in figure 10, there was no essential alteration in the character of the curves in response to the test meal whether the alkalis on the distal side of the pylorus were present or absent. There was the same preliminary rise in the total acid and combined chlorine curves. Subsequently, there was the same increase in the free acid value followed by a decrease to the point of complete neutralization. This final drop in the free acid value was accompanied by a terminal rise in the combined neutral chlorine value whether the duodenal alkalis were present or absent (fig. 10). This procedure was associated with the production of ulcers in the anastomosed jejunum, as occurred in all the experiments with the original type of duodenal drainage operation.

In the second procedure, using the original type of surgical duodenal drainage, fractional gastric analysis showed that the operative procedure had established an impediment to normal emptying. The essential character of the curves was the same before and after operation. The post-operative studies, however, revealed marked retention of the acid chyme in the stomach at the end of the cycle. In the normal dog the stomach was completely empty shortly after the appearance of free acid. During the period when free hydrochloric acid was present, decreasing quantities of juice, from 30 to 5 cc., were aspirated every fifteen minutes until neutralization was attained. After this type of operation, the stomach remained distended with fluid for a prolonged period, 230 cc. of acid chyme being drawn off late in the free acid period in one instance (fig. 11). After this procedure, Morton observed the change of acute traumatic lesions of the gastric mucosa into chronic peptic ulcers. As

Fig. 11.—Duodenal drainage, late retention of chyme with anastomosis performed at the pylorus, with consequent prolonged exposure of traumatic lesions to normal acid peptic activity.

traumatic lesions healed in the normal dog, the formation of these ulcers was associated with prolonged exposure of the lesion to normal acid chyme.

In the third procedure the alkaline secretions of the duodenum were drained back into the fundic portion of the stomach, as described in the preceding study; the usual types of peptic ulcers were formed in the anastomosed jejunum in a high percentage of experiments. The results of the fractional studies in this procedure are significant as they show the persistence of acid peptic activity after the introduction of duodenal alkalis into the stomach.

Postoperative fractional test meals on three dogs revealed the usual characteristic curves of normal digestion, with average normal values

for free acid at the end of the period; namely, values of from 20 to 30 expressed in terms of cubic centimeters of tenth-normal sodium hydroxide. Figure 12 shows the same preliminary rise in the value of the total acids and neutral chlorides, followed by the usual type of curve for free acid. There was the terminal rise in the value of the neutral chlorine in both instances, before and after operation.

Two other phenomena were observed which may have some influence on the development of these ulcers. One was the elevation of the rate of the basal secretion of acid, and the other, the influence of hemorrhage on secretion.

Basal Secretion of Acid.—During the period when the dogs were eating poorly and they had lost considerable weight, presumably the stage of ulcer development, an increased quantity of the resting basal

Fig. 12.—Perforated ulcer; the same character of curves was observed before and after surgical drainage of duodenal alkalis (gastric) into the fundic portion of the stomach.

secretion developed suddenly. The usual response to the test meal was observed, but following the completion of the digestive cycle a continuous secretion of juice of considerable acidity persisted (fig. 13). This change was not related in any way to a disturbance of the duodenal secretions because it was observed in dogs in which the alkalis drained into the distal part of the ileum, in those in which the alkalis were drained back into the stomach, and also in those in which gastrojejunostomy has been performed. This increased secretion was induced in a normal dog by a fast of seventy-two hours. It is probable that the phenomenon is related to this normal physiologic response to food after a prolonged fast, in which a high basal secretion is continued long after the digestion of a meal is complete.

Hemorrhage.—The other phenomenon was the association of hemorrhage with high acidity. Blood was aspirated from the stomach of three

dogs. In the first dog there was an absence of acid during a study of the stomach while fasting, and suddenly blood was present as the result of trauma. Immediately afterward, acid of considerable concentration appeared (50 tenth-normal hydrochloric acid). From a second dog 30 cc. of coffee ground material was obtained on a single aspiration of the stomach while fasting, with a free acid value of 60 tenth-normal

Fig. 13.—Duodenal drainage; continuous secretion of free acid after the completion of the normal response to a test meal (at two hour point) in a cachectic, ulcer-bearing dog.

Fig. 14.—Hemorrhage (isolated); first specimen: single appearance of blood and free acid during a course of hourly aspirations; second specimen: single aspiration of coffee ground contents of high acid value.

hydrochloric acid (fig. 14). In a third dog continuous bleeding occurred for the major portion of a twenty-four hour period of fast. There was a definite relationship between the appearance and disappearance of blood and the concentration of the free acid of the gastric contents (fig. 15). It is difficult to judge how much a high basal rate of secre-

tion, as mentioned, may have been responsible for this continuous secretion, but the three observations suggest strongly that blood may act as an adequate stimulus to the secretion of hydrochloric acid.

COMMENT

These studies show that in all the procedures used to produce experimental ulcers, the chemical characteristics of the gastric contents are unaltered. Whether the duodenal secretions beyond the pylorus are partially or wholly removed, or whether they are shunted from the duodenal to the gastric side of the pylorus, the concentration of the acid of the chyme that passes the pylorus remains constant. Consequently, all these ulcers have occurred with the passage of chyme of normal acidity by the pylorus into a segment of intestine where their action is not

Fig. 15.—Continuous presence of blood in gastric contents aspirated hourly, from A to B, associated with persistent free acid.

terminated by the duodenal alkalis normally present on the distal side of the pylorus.

This constancy of the chemical constituents of the gastric contents, whatever the degree of disturbance of the alkaline factors on the distal side of the pylorus, is not in accordance with Boldyreff's theory of the control of gastric acidity by regurgitation of these alkalis. Whether part or all of the duodenal secretions are eliminated, there is no tendency toward a condition of hyperacidity in the stomach. There is the same adequate control of the acidity of the gastric juice, without evidence of a compensatory mechanism. Hence it would appear that there is a mechanism for the control of the acidity which is entirely intragastric and wholly independent of the regurgitation of duodenal alkalis back into the stomach, and that these experimental ulcers have resulted from the acid peptic activity of normal chyme which was not terminated beyond the pylorus because of the absence of neutralizing alkalis.

As established by the results in the first procedure, the ulcers which developed beyond the pylorus in a moderate percentage of instances following ligation or transplantation of the bile or pancreatic ducts singly, partial hepatectomy and Eck fistulas are dependent on the action of normal gastric chyme, and a partial deficit of the duodenal juices. These ulcers have been produced in a much higher percentage of experiments by establishing a complete deficit of the alkalis beyond the pylorus following transplantation of both ducts, or by doing surgical duodenal drainage. With a gradually increasing acid peptic activity beyond the pylorus, due to the constancy of the chemistry of digestion and the decreasing amount of alkali beyond the pylorus from these procedures, there is a directly increasing tendency to the formation of ulcers. In other words, there appears to be a graded tendency toward the formation of ulcer, directly proportionate to the alkali deficit beyond the pylorus.

Seeking a possible clinical application of these purely experimental facts, it is interesting to speculate whether clinically: (1) duodenal ulcers might result from a deficit of alkali on the distal side of the pylorus associated with disease of the liver, pancreas or gallbladder, which allows the acid peptic activity of the chyme to be sufficiently uncontrolled so as to ulcerate the duodenal mucosa; (2) hypersecretion and hyperacidity of juice of 95 tenth-normal hydrochloric acid might be uncontrolled by the normal quantity of alkaline secretions in the duodenum and thus produce ulcers, or (3) the immunity of the mucosa of the first portion of the duodenum can be lowered by such a mechanism as the toxins of a burn, or the localization of streptococci, so that it becomes susceptible to the degree of acid peptic activity which persists normally in the first portion of the duodenum before the chyme is completely neutralized by the alkalis of the duodenum, and is ulcerated by it.

In the second procedure an extraneous factor has been introduced, whether from nerve injury or from some degree of stenosis of the pylorus associated with end-to-end anastomosis. This factor acts as an impediment to normal emptying. Consequently, the mucosa of the stomach is exposed to normal acid peptic activity for a prolonged period. This fact establishes the basis of Morton's experimental gastric ulcers. He showed that traumatic lesions of the gastric mucosa, which healed rapidly in the normal dog, tended to develop into chronic gastric ulcers after surgical duodenal drainage. He also observed by roentgenologic study that there was slight gastric stasis during the first two weeks, and that this subsequently increased. These fractional test meal studies have shown that whereas traumatic lesions of the gastric mucosa tend to heal readily when exposed to normal acid peptic activity for a normal period, when exposed to normal acid peptic activity for a prolonged period as a result of stasis they tend to change to chronic peptic ulcers. Since the

only demonstrable variable following this operation is this prolonged exposure of the lesion to normal acid peptic activity, it is probable that the destructive activity of acid pepsin over a long period was responsible for the development of these gastric ulcers. This concept is in accord with Hughson's conclusions when he showed, after a series of roentgenologic studies on the emptying of the stomach, that in animals in which delay is demonstrated ulcerations remain active at least twice as long as in the group in which emptying is more rapid.

The demonstration that experimental gastric ulcers are associated with prolonged exposure to the normal acid chyme suggests hypothetical conditions that might lead to the development of gastric ulcers in clinical cases. A traumatic lesion of the gastric mucosa, associated with pylorospasm and prolonged retention of the fluid chyme of normal digestion, might result in a gastric ulcer. With lowered immunity of the gastric mucosa, for a prolonged period of time, by such an agent as the localization of streptococci, the normal acid peptic activity of digestion, together with the mechanical factors of the region, might initiate a lesion and produce a chronic peptic ulcer.

The persistence of normal values for acid in the third procedure, despite the drainage of all the duodenal alkalis into the fundic portion of the stomach, is an unexpected observation which may possibly be explained by an increase in the amount of acid secreted, to compensate for these alkaline juices. Whatever the explanation, the question is raised as to whether the favorable results following gastro-enterostomy for clinical ulcers may be due not so much to the neutralizing effect of these juices as to the mechanical drainage of the free acid aliquot which terminates the digestive cycle. It may be that, with the relaxed state of the musculature at the end of digestion, all the final free acid which usually coincides with the period of distress may drain through the relaxed stoma and thus spare the ulcer from its destructive action. This result supports the idea that normal acid pepsin, acting in the absence of an effective neutralizing mechanism, is the probable cause of these experimental ulcers. They are not due to the loss of any specific protective activity of the juices other than chemical, because, in this third procedure, all the duodenal alkalis are present at a point proximal to the site of ulcer formation where they do not alter the normal chemistry of digestion, and are displaced only from the point of effective neutralization in the duodenum.

Experimental data support the clinical impression that hemorrhage may stimulate the secretion of an amount of acid that will have a deleterious effect on an ulcer. Likewise, a high rate of basal secretion of acid may develop which will be equally harmful to an ulcer.

Since it has been shown that normal acid peptic activity is the chemical factor associated with the production of these experimental ulcers,

one fact is revealed which is of major clinical significance: the graded immunity of the upper intestinal tract to the destructive action of the gastric juice, or, conversely, the increasing vulnerability of the mucosa to the formation of ulcer as the distance from the cardia of the stomach increases.

Under the mechanical conditions of these experiments the gastric mucosa did not ulcerate from exposure to the normal autolytic action of the juice for normal periods of time. Even traumatic lesions in all parts of the mucosa healed when exposed to acid pepsin for the normal periods of digestion. Furthermore, the inherent immunity of the mucosa to this action is so marked that it never ulcerated spontaneously from prolonged exposure to this activity as resulted from surgical duodenal drainage. Even with prolonged exposure to this autolytic activity after surgical duodenal drainage traumatic lesions in the cardia healed successfully. Similar lesions in the prepyloric segment, which is the site of clinical formation of ulcer, developed into chronic ulcers from this prolonged exposure; but here there are also mechanical factors involved which tend to prevent the healing of such lesions.

The duodenal mucosa ulcerated spontaneously from exposure to unneutralized acid chyme of normal digestion (in the absence of alkalis after surgical duodenal drainage) in a fair percentage of experiments. The jejunal mucosa ulcerated in practically all instances when exposed to this activity under the same experimental conditions. The contrast between the immunity of the gastric mucosa and the susceptibility of the duodenal mucosa to spontaneous ulceration probably explains the clinical preponderance of duodenal over gastric ulcers in a ratio of four to one, provided the initial lesion is established as frequently in the stomach as in the duodenum. This gradient of immunity would also explain the tendency for gastrojejunal ulcers to form in the relatively unfavorable environment of gastrojejunostomy, the low percentage of occurrence being dependent on unrecognized factors.

It is not necessary to postulate a state of hyperacidity to explain the formation of chronic ulcers. They have resulted experimentally from exposure to normal acid pepsin for the remarkably short periods of normal digestion, under proper experimental conditions. It is probable that, since meat is progressively disintegrated to a fluid state by acid in combined form during early digestion, the devitalized cells of an ulcerating lesion may be somewhat susceptible to the action of this combined acid and pepsin of early digestion. Probably the action is not so marked as from the free uncombined acid of late digestion.

SUMMARY OF STUDY II

In a long series of experimental studies, Mann and his co-workers have produced typical peptic ulcers by injuring the neutralizing mechanism in the duodenum, so that the acid chyme from the stomach

could act on the mucosa without hindrance. In earlier studies I found that the mechanical factors active in producing these ulcers, and presumably influencing clinical ulcers, were the force of the stream ejected through the pylorus, the friction of coarse cellulose food and the vigorous motor activity of the prepyloric segment.

Using a method of fractional gastric analysis which I devised for use on the dog, the underlying chemical factor in the production of these ulcers was shown to be normal acid peptic activity. The ulcers produced exhibit the highly destructive character of the gastric chyme. Of great significance is the gradient of immunity of the mucosa of the intestinal tract to ulceration, which probably is the deciding factor in determining the greater frequency of duodenal ulcer as compared to gastric ulcer, and the tendency for jejunal ulcer to develop following gastro-enterostomy.

These studies demonstrate that the gastric mucosa possesses considerable immunity to the autolytic activity of the acid and pepsin secreted by the stomach, whether exposed to it for a normal period or for a prolonged period, because spontaneous experimental ulcers of the chronic type produced in these experiments never developed in the stomach. Likewise, the normal duodenal mucosa is completely immune to this activity under the condition of a normal relationship between the acid chyme ejected through the pylorus and the neutralizing secretions present in the duodenum.

With slight disturbances of the interrelationship of normal functions in the pyloric region, the ordinary factors active in this segment assume pathologic significance. By experimentally disturbing these relationships, a considerable body of evidence has been developed which stands in answer to Cohnheim's statement that the real difficulty is in determining "the unknown something which prevents the healing of ulcer." The evidence indicates that the "unknown something" may be the normal acid peptic activity of the gastric chyme with the mechanics of the region, which act as a definite handicap once a lesion has been established.

III. AUTOLYSIS OF THE STOMACH

Gastromalacia, or self-digestion of the stomach, is a phenomenon, the occurrence of which during life has been much disputed by pathologists. If the occurrence of autodigestion were possible, one might consider it related to the formation of ulcer so far as one would represent a generalized and the other a localized digestive process. In either case the process could be attributed to an abnormal activity of the digestive enzymes, or to a deficiency of the tissues for natural self-protection against enzymatic activity. That there is such a relationship between autolysis and the formation of ulcer is suggested by the possible occurrence, as reported here, of generalized autolysis of the stomach following surgical drainage of the duodenal juices back into the stomach: the

procedure which resulted in the formation of ulcer. Because of this probable relationship, a brief review of general autolysis and of the resistance of living tissue to gastric digestion is relevant.

The literature contains few references to intra vitam autolysis of the stomach. Its occurrence after death has long been appreciated by pathologists. If an animal is killed at the height of digestion and kept warm, digestion of its stomach and adjacent tissues will take place. Virchow, Elasser and Cohnheim agreed that this was always a cadaverous process. Rokitsansky maintained, however, that it occurred during life, particularly in the end-stages of extensive tumors of the brain. Cases reported from Ziemssen's clinic by Mayer and Leube seem to bear out this contention. The mechanism of protection against autolysis has long been a source of speculation and study. Stah believed that the stomach was protected from autolysis by the sensitive soul; John Hunter¹²⁸ and Spallanzani believed that the vital power protected the body by some inherent energy. Bernard¹²⁹ was the first to view the problem in a physiologic manner, when he attributed this immunity to the fact that pepsin was not absorbed by the gastric mucosa (probably because of the mucous coat), and because any destroyed cells were rapidly regenerated. Harley ascribed the protection to the mucous film, and Pavy to the alkalinity of the blood, which neutralized the acid.

I found only one report of experimental gastric autolysis in the literature. Frouin¹³⁰ observed it while studying an isolated stomach with a fistula to the anterior abdominal wall. After transacting the cardia and pylorus, he anastomosed the esophagus and duodenum, so that the continuity of the digestive tract (with the stomach excluded) was reestablished. He closed the two ends of the stomach, and established a fistula to the anterior abdominal wall. Besides this surgical fistula, another smaller one formed accidentally between the cardia of the stomach and the esophagus. Through this fistula small quantities of food seeped into the stomach and were retained. The animal died on the twenty-ninth day, and necropsy was done within two hours. Almost complete digestion of the gastric mucosa had occurred. Frouin believed this resulted from stagnation of the products of protein digestion and gastric secretion. He repeated the study on an isolated stomach, administering salt to increase gastric secretion and injecting peptone into the stomach. Hemorrhage into the stomach resulted, which he assumed

would have resulted in autolysis if repeated often enough. In my study two cases of autolysis followed drainage of the duodenal juices back into the stomach, which caused an unbalanced intermixture of the digestive juices. In analyzing this phenomenon, the causative factors may be attributed to one of two factors: to increased enzymatic activity associated with prolonged retention of digestive juices which results from the procedure, or to deficiency in the normal protective mechanism of the mucosa.

The enzymatic activity of the digestive juices is analogous to the general autolytic or enzymatic activity elsewhere in the body. The analogy is similar to that existing between the endotoxins and ectotoxins of bacteria. Corresponding to endotoxins the tissues contain peptic, tryptic and ereptic-like enzymes which are active within the cell in metabolism, disease, involutional changes and death. Turck,³⁹ Effront and Robertson showed that these proteolytic intracellular enzymes belong to the same group as the digestive ferments. Analogous to bacterial ectotoxins are the enzymes of the gastro-intestinal tract, active outside the cell body, ordinarily inhibited from attacking the living mucosa, but reported in this paper to have possibly done so.

The first realization that the most constant tendency of tissue is toward spontaneous disintegration came, according to Levene,¹³¹ when Manassein and Buchner¹³² demonstrated a single substance in the cell which led to fermentation after the cell was crushed and dead. Salkowski¹³³ recognized that disintegration of liver, muscle and suprarenal gland was due to enzyme activity, and called the process "auto-digestion"; in 1900, Jacobi,¹³⁴ introduced the name "autolysis." An appreciation of the universality of this process soon followed. Mueller³⁶ showed that resolution in pneumonia was by autolysis, and Opie that the exudate was absorbed by the proteolytic activity of leukocytes. That pathologic processes represent only an intensified picture of normal protein metabolism by enzyme activity was first suggested by Dochez.¹³⁵ Flexner noted the intense self-digesting tendency in the organs of those who succumbed to typhoid and other infectious diseases. This process also occurs during life, in phosphorous poisoning, acute yellow atrophy, atrophy of the thymus gland, involution of the uterus and softening of tumors. Sykes and Meyers asserted that autolysis is a normal metabolic activity, for during a prolonged fast the amino-acid content of the blood

is maintained by autolysis of muscle protein. Notwithstanding the presence of destructive enzymes in all tissues, however, the organs succeed in guarding their integrity, as does the stomach, from enzyme activity. It is only when there is an exaggeration of the normal process, or a disturbance in the normal relationships which keep autolysis within bounds, that self-digestion ensues.

Bile may play a part in this process of gastric autolysis, as indicated by Tatum.¹³⁶ He cut blocks of various tissues and incubated them in fresh bile for from two to four hours at 30 C. They were sectioned and stained, and autolysis of the peripheral margins was found, with pyknotic nuclei which had lost their staining capacity for hematoxylin. No such effect was shown in dead tissue subjected to the same process. The action was accelerated by acid, but was inhibited by blood serum and alkali. In an effort to determine the constituent of the bile responsible for this phenomenon, he studied the effect of sodium glycocholate which he found less penetrating than either taurocholate or mucin-free bile, both of which had equal influence in causing the change. Unaltered bile was most penetrating. Boiling did not affect its influence, but animal charcoal diminished it. Bradley and Taylor¹³⁷ criticized this work because histologic changes were interpreted in terms of chemical action. They attributed the results to the solvent action of bile salts on the cell lipoids, claiming that the picture was that of cytolysis and not one of enzyme activity.

One of the possible variants that is of major importance in autolysis is the hydrogen ion concentration; this has been recognized as a controlling factor. Hedin,¹³⁸ among the earliest investigators, reported increased autolysis in an acid medium and decreased activity in an alkaline medium; he also reported that if the action is started in acid first and then transferred to alkali the autolysis is more complete than if acid acted alone. Morse¹³⁹ considered that autolysis is an autocatalytic reaction due to spontaneous increase in the hydrogen ion concentration. Bradley believes that the increase in the hydrogen ion concentration alters the proteins into forms more readily digested by enzyme activity. Dernby¹⁴⁰

found three distinct groups of proteolytic enzymes in the tissues, with end-products identical with those of pepsin, trypsin and erepsin of the gastro-intestinal tract, each acting at a different hydrogen ion concentration. In studying different tissues he found the stomach to contain a large amount of pepsin, with optimal activity in a hydrogen ion concentration range of from 2 to 3. This enzyme was present in all tissues, acting at an optimal hydrogen ion concentration of 3.5 and splitting proteins into peptones, but no farther. Trypsin-like and erepsin-like enzymes were present, acting in an optimal hydrogen ion concentration of 7.8, attacking only peptones and peptides, and yielding amino-acids. Self-decomposition of tissue proceeded best at a hydrogen ion concentration of from 5 to 6, that is, between the optimum for pepsin and trypsin. Bradley criticized Dornby for his use of the terms peptic, tryptic and ereptic enzymes, because he claimed these tissue enzymes have a different optimal hydrogen ion concentration than the digestive ferments. He found that tissue protease is inhibited at a hydrogen ion concentration of 2.6, which is optimal for pepsin, and that pepsin is least active at the optimal hydrogen ion concentration for tissue autolysis. He also found that the addition of trypsin carried the splitting of proteins beyond the point to which autolysis alone could carry it.

Another contribution on the influence of hydrogen ion concentration is the work of Rona and Mislowitzner in which they found that autolysis of the liver of guinea-pigs was maximal with acetate buffers of p_H from 3.5 to 3.8, and with phthalate at p_H 4.2. The action was arrested by changing it briefly to p_H 8. Most of the nitrogen in the autolysate was found in the form of polypeptides with 50 per cent autolysis; if the products of digestion were removed by dialysis, the digestion was increased to 90 per cent. Nagai,¹⁴¹ while studying the pancreatic juice, found that with increased acidity the initial velocity of autolysis was decreased, but that it recovered in a number of hours. He also found that increased alkalinity augmented the initial velocity, but that it soon fell, indicating destruction of the enzyme.

Thus it may be seen that surviving tissue variations in the hydrogen ion concentration can augment the destructive action of proteolytic enzymes. It may be that the abnormal chemical status which the present operative procedure establishes, with fluctuations from acid to alkali, renders the proteolytic enzymes of the digestive tract abnormally active, leading to digestion of the stomach. However, there is another factor that must be considered, that is, the possible impairment of the normal mechanism of protection against the action of these enzymes.

Bernard first demonstrated the power of the digestive juices to disintegrate living tissue by introducing the leg of a frog into a dog's stomach

141. Nagai, Kazuo: On the Autolysis of Pancreatic Juice, *J. Biochem.* 2:399, 1922-1923.

through a fistula and watching the digestion of it. Pavy found this to be true also of a rabbit's ear. He believed that in the wall of the stomach the alkalinity of the blood neutralized the hydrochloric acid. Schiff⁹² demonstrated that the mucous layer protects the stomach from pepsin by showing that the mucus which forms over the orifice of a canula placed in a gastric fistula will allow the passage of hydrochloric acid, but not of pepsin. De Klug,¹⁴² seeking to verify this protective rôle of mucus, made a powdery extract of intestinal mucosa which had all the characteristics of mucin; it inhibited the action of both pepsin and trypsin even when heated. The same inhibiting effect was demonstrated with mucus from bile, and with pseudomucin from an ovarian cyst. Palier¹⁴³ believed that the stomach did not digest itself because the mucus and peristalsis of the tract constantly repelled the digestive juices from the wall.

Weinland attributed this immunity to an antiferment contained in the gastric mucosa. Katzenstein stopped the digestion of spleen and living intestine by adding an extract of gastric mucosa to the gastric juice. Lecine and Hatz found that a fragment of gastric mucosa inhibited the digestion of egg white, which was not true of intestinal mucosa. Kawamura, studying this antiferment, took equal sized pieces of gastric mucosa, intestinal mucosa and spleen and added each to digesting gastric juice according to Katzenstein's conditions. The stomach slightly inhibited digestion, the intestine somewhat more and the spleen most of all. Blood serum also exercised a decided inhibitory effect on digestion. He concluded that there is an antipepsin in the blood, demonstrable in the gastric mucosa and other tissues, and that ulcer arises from a circulatory disturbance resulting in a lack of antipepsin in a circumscribed area of the stomach. All of these observers considered autolysis as due to a break in the equilibrium between enzyme and anti-enzyme, predisposed to by vascular changes and by traumatic and nervous lesions. Lieblin, studying the quantitative value of antipepsin in the blood, found it fairly constant in healthy and sick persons, but in cases of gastric ulcer it was inconstant, sometimes high and sometimes low.

Surgical procedures have been used to study this immunity of living tissue to digestion. Katzenstein introduced a loop in intestine into the stomach of a dog, and death resulted in eight days from digestion of the loop. He obtained the same result with a rat. He then anastomosed a resected segment of intestine at two points on the greater curvature, so that the gastric juice passed through it as a collateral canal. After several days the dog died with necrosis and digestion of the mucosa of

the implanted segment. The peritoneal surface of a loop of duodenum was implanted into an opening made in the pyloric antrum. This resisted digestion. Implanted spleen and omentum were promptly digested. Katzenstein concluded that the gastric mucosa contained antiferments which were not present in the intestinal mucosa. Lecine and Hatz, on the contrary, found that when great care was taken not to injure the blood supply, the spleen and loops of intestine could be implanted into the stomach without undergoing digestion. They concluded that a tissue which secreted a juice was protected from its action. Stewart suggested that various body membranes have developed a specific resistance to the fluids with which they normally come in contact, but not to other juices. Matthes believed that the gastric mucosa had developed a special resistance to hydrochloric acid, which he claimed was destructive to other tissues.

Dragstedt and Vaughan⁷⁰ transplanted flaps of the lower part of the duodenum, and of the upper part of the jejunum, ileum and colon into the pyloric region with the blood supply intact, and the transplant had not digested at the end of three months. If these patches were sutured with the serosa toward the lumen, the serosa and the muscularis were digested, but the mucosa remained resistant. A split spleen was implanted with its raw surface toward the lumen. It was not digested even though it did not have a mucous coat; also, epithelium grew inward covering its edges. This, it was claimed, ruled out any protective function by the mucous coat, and emphasized the intrinsic resistance of the naked exposed living cell to digestion. Kawamura, using dogs, exposed parts of the stomach, intestinal wall and spleen to the action of gastric juice, but they were not affected while the circulation was unimpaired. Only after necrosis had begun as a result of circulatory disturbance was there any sign of digestion. As mentioned, de Takats and Mann, and later Morton, transplanted jejunal patches into the wall of the stomach. With the exception of one condition, they resisted digestion until after duodenal drainage had been established, which probably resulted in delayed emptying of the chyme and, consequently, prolonged exposure to the acid chyme. Mann also transplanted loops of jejunum into the posterior wall of the stomach. These remained normal until the extirpation of the suprarenal glands, following which autolysis ensued.

METHOD

This study presents two instances of autolysis of the gastric mucosa. The phenomenon was unexpected and was observed after an operative procedure in the study of experimental peptic ulcer.

The operation consisted in draining the duodenal secretions back into the fundic portion of the stomach. The pylorus was severed, and the duodenal end was inverted. The jejunum was severed just distal to the ligament of Treitz.

The distal end was brought up and anastomosed to the open gastric end of the pylorus, thus reestablishing the continuity of the tract, with the duodenum excluded. The distal end of the isolated duodenum was anastomosed to the fundic portion of the stomach, so that the alkaline secretions were drained into that portion of the stomach (fig. 1).

In three of the dogs an effort was made to influence the autolytic process by the administration of different salts contained in capsules. Five grams of sodium chloride was administered to one dog three times a day. This was done because Frouin had administered the salt, and believed that it had increased the tendency to autolysis. To a second dog, 5 Gm. of sodium bicarbonate was given three times a day, on the chance that the process might be initiated by shifting the hydrogen ion concentration, even momentarily, to the alkaline side of neutrality. To a third dog, 5 Gm. of sodium taurocholate was given three times a day with the purpose of augmenting the action of the bile which was completely drained into the fundus of the stomach. Rywosch had produced inflammation and gangrene of the stomach of rabbits by feeding an excess of bile salts. The administration of the salts was continued over a period of a month, but in none of the three dogs did autolysis of the gastric mucosa develop.

RESULTS

Two of twenty-six dogs subjected to the foregoing operative procedure died suddenly. Necropsy revealed extensive autolysis of the gastric mucosa. The first dog died twenty-three days after operation, during which period it had lost 1.8 Kg. At necropsy, both lungs were collapsed and the pleural cavities contained a considerable amount of thin chocolate-colored fluid which was strongly acid. The mediastinum had been entirely eaten away, except for the main blood vessels, the trachea and the lower part of the esophagus. The upper and intrathoracic portions of the esophagus had been entirely eaten away. This explained the fluid in the chest, which, being strongly acid, was probably gastric juice. The digestion had extended through the structures of the neck, and the upper limit was determined by the lower part of the skull. The whole hand could be inserted into the cavity in the neck. The peritoneum was clean and relatively free from adhesions. The stomach had undergone considerable digestion at the points adjacent to the stoma and to the delivery of the duodenal contents. The digestion had entirely destroyed the mucosa, leaving the submucosal vessels standing by themselves. The stomach contained coffee ground material. All anastomoses were satisfactory.

The second dog died five months after operation; it lost 1 Kg. Necropsy revealed autolysis of the stomach and jejunum, and ulcer formation. The peritoneum was clean, and all suture lines were intact. The walls of the stomach appeared thin and transparent as the organ was washed with water. When opened, extensive autolysis of the gastric mucosa was found. Over an area approximately 10 by 7 cm., the cardia was denuded of mucosa, and the glistening submucosa formed the inner lining of the stomach. An area of jejunum close to the anastomosis,

about 2 cm. in width and extending about 5 cm. in a longitudinal direction, was likewise denuded of mucosa. In the center of this autolyzed area, two perforated ulcers were found (fig. 16). The relationship of the autolyzed surface and the ulcers suggested a possible identity between the mechanism that leads to a localized area of destruction, as an ulcer, and that which leads to extensive autolysis of the gastric mucosa.

COMMENT

It is impossible to estimate the significance of the results. They are isolated phenomena in an uncontrolled experiment. It is not possible to judge how much of the process is *intra vitam* and how much is post-mortem change. It is significant, however, that autolysis occurred in

Fig. 16.—Extensive area of autolysis of the mucosa, *a*, of the stomach and jejunum, associated with the formation of perforated ulcers, in an experimental study in which the duodenal alkalis were drained back into the fundic portion of the stomach.

two animals subjected to the same operative procedure, and that they were isolated specimens in a large group of normal and experimental animals all receiving the same kennel care. Shortly after death, all animals were placed in refrigeration. Routine careful investigation of all organs was carried out, and never was this phenomenon observed. It seems fair to assume that the operative procedure established conditions that were conducive to the initiation of the autolytic process.

Conclusions cannot be drawn concerning the relationship of this process to that of general tissue autolysis. In both instances comparable enzymes are active, in the one instance within the cell and in the other instance outside the cell. General autolysis is definitely influenced by

shifts in the hydrogen ion concentration of the environment, and in these instances of autolysis of the mucosa of the stomach there is the possibility of a widely shifting hydrogen ion concentration. It is interesting to speculate whether the conditions of the experiment made it possible for the intragastric enzymes to attack the gastric mucosa. If this is true, it is possible that an ulcer may represent a similar process limited to an area of lowered resistance.

Why does not the stomach digest itself ordinarily? What is the source of protection against this destructive process? This seems to be a problem more open to theory than to exact investigation. In a series of studies which I made on the control of the acidity of the gastric juice, it seemed that in the active state of digestion food combined readily with the acid, and that after the completion of digestion the residual free acid was emptied from the stomach. It appeared that in the resting state the rate of secretion was lowered to a level at which, according to Foster's evidence, it may be combined with the mucus in the presence of pepsin at body temperature. This reaction may take place immediately in the lumina of the glands in the fundus. The gastric mucosa would probably be protected from any residual free acid in the lumen of the stomach by a coating of this mucus capable of combining with the acid.

SUMMARY OF STUDY III

The literature contains little on autolysis of the stomach. Two such instances, observed in an experimental study, are reported. There may be a general analogy between intracellular enzymatic activity responsible for general autolysis and the extracellular enzymatic activity responsible for the instances of autolysis of the gastric mucosa. This process may represent the mechanism by which isolated ulcers of the mucosa are established, when there is local reduction in the immunity of the mucosa to this autolytic activity. It is probable that the mucous secretion of the stomach by virtue of its capacity to combine with free acid forms the principal defense of the gastric mucosa against autolysis.

LOOSE CARTILAGE FROM INTERVERTEBRAL DISK SIMULATING TUMOR OF THE SPINAL CORD*

WALTER E. DANDY, M.D.

BALTIMORE

The two loose cartilages here reported were disclosed at operation for presumed tumors of the cauda equina. In each instance the spinal canal was completely blocked as shown by the shadows of iodized oil 40 per cent (figs. 1 and 2). The signs and symptoms were so rapidly progressive and the pain in the spinal column so severe that presumptive diagnoses of carcinoma of the vertebra were made. The fact that the two cases appeared only a few months apart leads me to believe that the lesion may not be so infrequent, although a review of the literature has failed to disclose other cases of their kind. The lesion is a completely detached fragment of cartilage from an intervertebral (lumbar) disk and is surrounded by serum. It bulges dorsally into the spinal canal as a tumor, and by compressing the roots of the cauda equina causes motor and sensory paralysis, loss of reflexes and of rectal and vesical control. The lesion is undoubtedly of traumatic origin.

REPORT OF CASES

CASE 1.—A sparsely nourished man, aged 47, was referred by Dr. Lewellys F. Barker. Whether or not the past history was relevant to the present illness was not clear at the time. Three years earlier a tumor had been removed from the hand; a microscopic diagnosis of a sarcoma was made. The scar on the hand, the regions of the epitrochlear and axillary glands, had since been treated intensively with radium. Subsequently an axillary gland was removed, but no sign of malignancy was discovered. Two years later, he consulted Dr. Barker because of convulsions which dated back two years.

The patient was readmitted to Dr. Barker's service on May 15, 1928, with an entirely different complaint. Ten weeks before admission he had a severe attack of pain in the lumbar region and both hips; there was more pain in the right hip. The pain radiated down the back of both legs, with more pain in the right leg. After two months of excruciating pain, it was necessary to resort to morphine for relief. Six weeks before admission to the hospital, a "dead feeling" developed in both legs and gradually increased. Two weeks before, he was barely able to stand alone. Assistance was necessary to walk a short distance. One week before, retention of urine and feces developed; after that time he was catheterized twice daily. He lost 42 pounds (19.1 Kg.) in weight, 15 pounds (6.8 Kg.) of which were lost in the last two months before admission. Pain in the lumbar region, hips and legs steadily became more severe.

On admission to the Johns Hopkins Hospital, the patient was found to have a total flaccid paralysis below the knees. Except for feeble flexion and extension

* Submitted for publication, April 29, 1929.

* From the Johns Hopkins University and Hospital.

of both legs at the hips, the legs were useless. Sensation was impaired though not entirely lost; sharp and dull stimulation were not differentiated. Vibratory sense was lost. Flexion and extension of the toes could not be differentiated, though the patient could tell which toe was touched. There was loss of sphincter control of feces and urine (retention of urine was complete). Marked tenderness, even to light pressure, was noted over the spine of the third and fourth lumbar vertebrae. The lumbar muscles were in continuous strong spasm. Movements of the spine were painful, and even coughing intensified the pain. The patient was averse to any movement, and flexion of the knee was painful.

Fig. 1 (case 1).—Shadow of iodized oil at the upper margin of the tumor caused by a loose cartilage of the intervertebral disk.

The abdominal reflexes were normal; the cremasteric reflexes were not obtained, and the knee jerks were subnormal. The Achilles jerks were not obtained, and there was no ankle clonus. The Babinski, Gordon and Oppenheim tests were negative. The Wassermann reaction of the blood was negative. Roentgenograms of the lumbar spine were negative.

Through a cisternal puncture, 0.5 cc. of iodized oil was injected. It stopped abruptly at the level of the third lumbar vertebra.

Preoperative Impression.—The rapidly progressive paralysis, sensory, motor and sphincter, the severe pain and tenderness in the back, the great loss of weight and finally the history of a malignant lesion of the hand (doubtless incorrect) led

me to suspect a metastatic lesion of the third lumbar vertebra, despite the absence of signs of destruction in the roentgenogram.

Operation.—It was decided to explore the lesion to be sure of its character, and if it was malignant to perform a chordotomy. The laminae of the third and fourth lumbar vertebrae were removed. No change in the amount of extradural fat was observed. When the dura was opened, the roots of the cauda equina herniated markedly (fig. 3). The nerves were greatly injected, and because of this increased vascularity, oozing followed when they were touched. It was seen

Fig. 2 (case 2).—Iodized oil shadow at the upper margin of the tumor.

that there was a sharp knuckle of the roots protruding backward. Above and below this knuckle, there was a sharp drop. Palpation revealed a hard tumor lying beneath the roots and pushing them through the dural opening. The roots were then retracted to the left, and a bulging tumor mass was seen. It was round, about as large as a big hazelnut (about 1.5 by 1.5 cm.) and entirely covered by dura. It seemed semifluctuant when touched with the point of the forceps. The lesion was still thought to be malignant, even though the ventral dura was intact. After some hesitation I thought it advisable to incise the dura, and much to my surprise a border of loose cartilage protruded through the opening (fig. 4). With forceps, the cartilage was picked up and delivered without resistance. It was roughly oval, but crumpled. When straightened, it measured 2 by 0.8 by 0.3 cm. Its edges

Fig. 3—Drawing showing the roots of the cauda equina bulging backward.

Fig. 4—Cauda equina retracted exposing tumor on ventral surface of the canal. The tumor has been incised and the loose cartilage is being delivered.

were very irregular, almost serrated (fig. 5). It had no attachments to the vertebral cartilage. Exploration of the cavity with a small curet revealed no additional sequestrums either of cartilage or of bone. A few drops of fluid escaped with the "floating cartilage." On gross inspection, there was no evidence of bone.

Microscopic Report.—A few scattered cartilage cells in varying states of degeneration were scattered through a pink-staining hyaline mass which was not entirely homogeneous, but in places was broken up by scattered fibrils longitudinally arranged. There were no inflammatory changes. No round or polymorphonuclear cells appeared in the sections, and there were no bone cells or deposits of calcium.

Postoperative Course.—Recovery from the operation was uneventful. The pain, though immediately relieved, was not at once abolished. Gradually it became less and less, and in a few weeks ceased. Vesical control was regained in two weeks and rectal control four weeks after operation. Return of motor power began seven weeks after the operation (three weeks after leaving the hospital). In a letter written six months after the operation, the patient stated that he could walk long distances without support, and every week improvement continued.

Fig. 5.—Loose cartilage removed from patient in case 1.

Subsequent History.—After the nature of the lesion was known, the recent history was again reviewed for trauma. The patient then recalled a severe, sharp lumbar pain which came with a sudden jolt when he was riding horseback three months before, or about two or three weeks before the onset of his present illness. He had forgotten the pain, since it disappeared after a few hours and had not returned during the succeeding days.

CASE 2.—A large, robust man, aged 61, was referred by Dr. Eugene V. Parsonnet of Newark, N. J., because of paralysis of the lower limbs. He had been in perfect health until twelve weeks before, when he pushed his automobile out of the driveway. Immediately afterward, a dull, heavy pain developed in the small of the back. He went about his duties, and in a few days the pain abated. A week later, without appreciable cause, a sudden excruciating pain struck the lumbar region and radiated down the posterior aspect of both thighs. The pain was so severe that he had to remain in bed for two or three days. Movement of the spine caused severe pains. A few days later, he was again relieved, and returned to work. Ten days after the second attack, he was seized with a third and even more severe pain at the same site and with the same referred distribution.

At this time (about a month after the first pain), he was seen by Dr. Parsonnet, who noted the following: 1. The normal anterior lumbar curve was missing.

2. There were definite scoliosis of the lumbar spine to the right. 3. Marked spasm of the erector spinae muscles. 4. Moderate tenderness at the third and fourth lumbar spinous processes. 5. The right knee jerk was diminished and the right ankle jerk absent. The patient was able to stand, but any movement elicited great pain.

An orthopedic consultant was called who advised stretching the sciatic nerves. This was done under deep anesthesia with ether. A plaster jacket was applied with the back in hyperextension. The spica extended to the toes of the right foot; the left leg was left free. On recovery from the anesthesia the patient was unable to void, but this was considered a sequel of the anesthesia. Three days after application of the cast, loss of power developed in both feet; he was unable to flex the toes. A slight edema of the left ankle (not included in the cast) developed.

Fig. 6.—Remains of cartilage cells. There are no evidences of inflammation.

Two days later (five days after the cast had been applied), he could not move his left leg (the right was in the cast) and there was incontinence of feces. On the following day, the cast was removed.

A neurologist who was called in consultation noted the following: 1. There was loss of deep and superficial sensation from the toes to the hips and loss of sensation around the anus. 2. The patient was unable to make any movements of either foot or leg below the knee. He could flex and extend the leg at the hip. This was some improvement, for two days earlier he was reported to be unable to make any movement of the leg. Paralysis was of the flaccid type. 3. Examination of the reflexes showed the ankle and right knee reflexes absent, the left knee reflex was diminished, and the abdominal and cremasteric reflexes were normal. 4. There was loss of vesical and rectal control. 5. Tenderness persisted over the third and fourth lumbar vertebrae. A lumbar puncture was done; the fluid was clear and colorless and registered 10 mm. of pressure with the mercurial manometer; jugular compression (Queckenstedt test) caused the pressure to rise instantly

to 30 mm., and on release of jugular pressure, the fluid promptly fell to the former level. The cell count was normal and there was no increase of globulin.

The patient was referred to me twelve weeks after the strain in the back and three weeks after the sciatic nerves had been stretched and the cast applied. The physical and neurologic observations were essentially the same as those just reported: 1. Sensation of every form was absent below the third lumbar segment but it was normal above this segmental level. 2. Flexion, adduction and extension of the leg at the hips were possible but decidedly weak while abduction was absent; there was no movement at the knee, ankle and toes. 3. All reflexes were abolished at and below the knee. 4. There was complete loss of vesical and rectal control. Lumbar puncture showed definite xanthochromia, the fluid having a greenish-yellow tint. The cell count was 10. The Queckenstedt test was negative, the column of fluid rising and falling with application and release of jugular compression. Iodized oil was injected; it descended only the distance of half a vertebra, lodging at the level of the fourth lumbar vertebra (fig. 2).

The only abnormality that could be detected in the roentgenograms (anteroposterior view only) was a supernumerary lumbar vertebra. The intervertebral disks appeared normal in size and shape.

Preoperative Impression.—That a tumor completely blocking the spinal canal was present at the level of the third lumbar vertebra seemed certain. That there was a definite relationship to the "stretching" of the sciatic nerves because of the sensory, motor and sphincter loss that occurred promptly thereafter could hardly be questioned. But it was necessary to admit that there was a preexisting lesion which had caused the severe pain in the back and down the legs. Though a metastatic lesion of the vertebra was suspected, no destruction of bone could be seen in the roentgenogram and no primary carcinoma could be found, though carefully sought. The true nature of the lesion was not suspected.

Operation.—Laminae of the fourth and fifth lumbar vertebrae (corresponding to the normal third and fourth) were removed under rectal ether anesthesia. Before the dura was opened, one could feel a hard mass about 1.5 cm. long, but when it was opened no tumor was visible. The roots of the cauda equina covered the exposed field. However, a sharply defined hillock of the cauda equina pushed backward, and under it one could still feel tumor of bony hardness. The roots of the cauda equina were definitely reddened and swollen. The cauda equina was retracted from the right side with a blunt dissector and a well circumscribed bulging extradural mass was at once visible; it crossed the midline posteriorly but was more on the right than the left. The mass was white, being covered with intact dura. When pressed firmly with the end of the forceps it seemed to fluctuate; at least it was soft in the center where it gave evidence of pointing. At once the picture of case 1 was recalled to mind for the gross appearance of the swelling was the same in both cases. The dura was slit longitudinally for a distance of about 1 cm. It was entirely avascular. A piece of loose cartilage projecting into the dural opening was picked up with the forceps and easily delivered (fig. 7). It was entirely unattached and no force was required to withdraw it. A few drops of fluid escaped with the floating cartilage. Further exploration of the cavity was not attempted. The borders of the cartilage were irregular; there was no sign of infection, no redness of the cartilage and no redness of the dura which covered the tumor. No fragments of bone were found attached to the cartilage. The cut edges of the dura sank back into the cavity from which the cartilage was removed. The knoll of the cauda equina entirely disappeared. The alinement of the vertebrae was normal.

Microscopic Report.—Exactly the same microscopic picture presented as in the preceding case. A few scattered cuts of cartilage were present, though in varying degrees of preservation. There was no cellular reaction indicative of an inflammation.

Subsequent Note.—The patient's recovery from the operation was uneventful. Urinary control returned ten days, and rectal control one month, after operation. Some sensation had returned within a month. He was beginning to walk four months after operation. Doubt of eventual complete recovery of motor function as in case 1 can scarcely be entertained, for the nerves are intact and apparently uninjured.

ANALYSIS OF CASES

In each case a large fragment of the intervertebral cartilage had become detached and was acting as a sequestrum. The reaction to the "foreign body" caused a swelling which bulged dorsally into the spinal canal (fig. 8). Pressure on the roots of the cauda equina then produced paralysis of all function below the nerve level of the tumor and through edema some function was lost for distance above the tumor.

Fig. 7.—Loose cartilage removed from patient in case 2.

The detached cartilage is almost certainly the result of trauma, but a relatively trivial trauma. In the first case no history of trauma was given voluntarily; it was elicited only after trauma was suspected. The trauma in the second case was almost surely the slight wrench caused by pushing an automobile. Several attacks of pain identical in both character and location were again induced by slight trauma before the advent of paralysis, and the location of the pain remained the same after the paralysis developed. The severe trauma incident to "stretching the sciatic nerves" and to placing the body in the cast with the lumbar region flexed undoubtedly caused the lesion to fulminate and promptly to reach the stage of tumor formation some time in advance of the normal course of events.

The preoperative diagnosis of a lesion in the vertebra could hardly be questioned in either case, because the slightest movement of the lower part of the spine always brought on or intensified the pain. Moreover, the tense spasm of the erector spinae muscles and the sharply

localized severe tenderness of the spinous process offered supporting evidence of the strongest kind. In these respects the lesion is hardly different from carcinoma of the vertebra. In either condition, only the recumbent posture could long be tolerated.

In both patients, the pain radiated down the back of both legs but usually down one more than the other. The side most involved proved to be the side of the greater bulge of the tumor. These facts lead one to wonder whether bilateral sciatic pains do not in most instances indicate a lesion affecting the spinal cord or cauda equina, more frequently

Fig. 8.—Sketch to show conception of position and manner of formation of loose cartilage projecting into the spinal canal and compressing the cauda equina.

the latter. These cases at least offer pathologic evidence of a definite lesion inducing symptoms of so-called sciatica with its all too meager pathology.

That the floating cartilage in each of these cases was in the lumbar region is doubtless significant. The maximum effects of shocks and of torsion of the body are transferred to the lumbar spine. As protection against shocks, the intervertebral disks attain their greatest size in the lumbar region. That the lesion occurs about the middle of the lumbar spine is probably also because of an additional point of least

resistance, for here the maximum part of the anterior lumbar curve is attained. Certainly movable vertebrae on a curve offer the maximum opportunity for localized effects of trauma.

That the lesion occurs on the posterior instead of on the anterior aspect of the lumbar vertebra is probably also significant. The normal anterior curvature of the lumbar spine would be expected to throw greater localized effects of trauma on the posterior side of the disk. In other words, the cartilage should be more readily pinched posteriorly than anteriorly. Then, too, the relatively thin and incomplete posterior ligaments of the lumbar spine should more readily permit protrusion of a tumor in the intervertebral disk than the stronger and complete anterior ligament. Whether a loose cartilage could push through the strong and firmly attached anterior ligament can only be conjectured. There is as yet no evidence that a loose cartilage forms only in the posterior part of the disk though it may well be possible. From the size of the extended cartilage as seen at operation, it is hardly possible that more than a third or at most a half of the anteroposterior diameter of the disk can be involved.

Finally, in both instances the tumor presented not in the midline but to one side. Doubtless the explanation for this fact is that the posterior common ligament is defective laterally along the lumbar spine. Since the lesion is of traumatic origin it is probably not without significance that both of these patients are men. It is also not improbable that the additional lumbar vertebra in one patient may have had some part in making the lumbar spine susceptible to injury.

Emphasis has been placed on the seemingly trivial injuries that cause the cartilaginous sequestrum formation. It is not improbable that the repetition of minor traumas may, at times, at least, be an important factor. The history of the repeated attacks in case 2 suggests this possibility. There must be many instances in which the intervertebral cartilage sustains the degree and character of injury experienced in these two cases, and yet subsequently heals instead of going on to sequestration. It is difficult to believe that the complete detachment of the cartilaginous fragment does not require considerable time, and that with proper rest and fixation of the spine this outcome may be avoided. A remarkable contrast in the disposition of fragments of intervertebral cartilage is presented by severe fracture dislocations of the spine. There the cartilage is badly torn and frequently fragmented, but in the process of healing it is organized with bone and fibrous tissue into a solid mass.

The x-ray has disclosed nothing in either of these cases. After the character of the lesion was known, the roentgenograms were again inspected, with negative results. However, only anteroposterior views were taken before operation, and positive signs would hardly be expected from this view. However, shortly after operation on the

second patient, lateral stereoscopic views of the affected part of the spine were taken, and not the slightest defect could be seen. The absence of bone in the sequestrum might well preclude the delineation of the tumor.

DIAGNOSIS

It is not difficult to arrive at the diagnosis of a tumor of the cauda equina because of the progressive paralysis—sensory, motor and sphincter—and loss of reflexes. The rapid progression of these signs and the severe pain in the back, the rigid lumbar spine due to spasm of the erector spinae muscles and the marked tenderness over the spinus processes and laminae of the lumbar vertebrae are such as to make metastatic carcinoma of the body of the vertebra the most likely diagnosis. The absence of roentgenologic changes in the body of the vertebra would appear to carry much importance in the differential diagnosis between this lesion and metastatic carcinoma or sarcoma of the body of the vertebra. The malignant lesions are almost the only ones that offer difficulties in differential diagnosis.

Aside from the negative roentgen changes in the body of a vertebra, there seems to be no absolute differential objective evidence. Even the clinical and microscopic examinations of the cerebrospinal fluid may show no differences, for both lesions are extradural. Each may give a mild degree of xanthochromia and globulin increase. Both give a negative reaction to the Queckenstedt test if the block is caudal to the point of entry of the needle, and both show a complete block at the upper level of the tumor when iodized oil is injected.

In the differential diagnosis two considerations are all-important: (1) to make the clinical diagnosis of carcinoma only on absolute evidence, i. e., microscopic or roentgenologic, and (2) to accept the operative diagnosis of a malignant condition only on positive evidence. My willingness to accept suggestive evidence of malignancy nearly deprived the first patient of the opportunity of having the lesion explored. In fact, had he not been eager to grasp the faint hope which an operation offered, the lesion would not have been disclosed. Even at operation the bulging mass from the body of the vertebra was at first considered so surely malignant that there seemed little reason to open the tumor.

The order of return of the various functions is most interesting. In both cases the vesical control returned completely in about ten days. Rectal control returned in about one month in each instance. Sensation gradually returned in about a month, but motor power made no improvement whatever until from seven to eight weeks after the operation in the first case, and at the end of the second month the motor power had not yet returned in the second patient. In the first case the motor improvement came slowly and continued for several months.

RESEMBLANCE OF THIS LESION TO OSTEOCHONDritis DISSECANS
OR TRAUMATIC JOINT-MICE

Superficially at least, the loose vertebral cartilage appears to resemble the loose cartilage of the knee, elbow and ankle joint following osteochondritis dissecans described by König in 1888. They differ in that fragments of bone were not attached to the cartilage in either of my cases. The environment too is greatly different in that there is no cavity—even potential—as in the knee and elbow joints. More common in the knee joint than elsewhere, this condition has come to be recognized as a clinical entity, but the dividing line between osteochondritis dissecans and other joint-mice appears to be none too sharp. The distinction is usually made that in osteochondritis dissecans the loose bodies occur singly or at most in pairs, and that there is no evidence of inflammatory joint involvement elsewhere. König¹ could find no evidence of traumatic or constitutional origin and for that reason considered them to represent a distinct pathologic process. Barth² thought they were purely of traumatic origin. Ludloff, who first diagnosed them by roentgenograms and treated them surgically, thought that they were due to occlusions of end-arteries. Other authors (Freiberg and Wooley,³ Ridlon,⁴ Codman,⁵ Weil,⁶ Anglin⁷ and Troell⁸) have come to no more definite conclusion. Büdinger⁹ (1907), Axhausen¹⁰ (1914), Kappis¹¹ (1920) and Brackett and Hall¹² (1917) were more positive of their purely traumatic origin. They also called attention

to the fact that the injury may be slight and repeated. The present trend of opinion seems to be that the term *osteocondritis dissecans* is a misnomer (for there is no evidence of inflammatory character), and that it is better to classify these loose bodies under *traumatic joint-mice*.

SUMMARY

1. Following slight (or repeated) trauma a fragment of an intervertebral disk may become detached, and eventually bulge into the spinal canal as a tumor. The "tumor" is composed of the cartilage and fluid formed by reaction to the foreign body.

2. Two instances of this lesion are reported, both being disclosed at operation. Both are in the midlumbar region, and both occurred in men during the latter half of life.

3. The trauma at onset is relatively trivial and perhaps repeated. The lesion is probably similar to *osteocondritis dissecans* or *traumatic joint-mice* of the elbow and knee joint.

4. The early symptoms are those of localized vertebral pain plus bilateral sciatica—one side being affected more than the other. Later, the symptoms are rapidly increasing paralysis, sensory and motor paralysis and loss of urinary and vesical control and of reflexes—all due to compression of the cauda equina.

5. The signs and symptoms suggest carcinoma of the vertebra. This preoperative diagnosis was made in both cases.

6. This lesion offers a pathologic basis for cases of "so-called sciatica," especially bilateral sciatica.

7. The lesion is cured by operative removal of the cartilage.

RENAL COUNTERBALANCE *

JAMES J. JOELSON, M.D.

CLAUDE S. BECK, M.D.

AND

ALAN R. MORITZ, M.D.

CLEVELAND

The theory of renal counterbalance was introduced by Hinman¹ in 1922. Before this article appeared, little, if anything, had been written concerning the possibility of renal atrophy of disuse, and according to Hinman this type of renal atrophy was a new conception, even though a similar process had long been recognized in other organs, such as muscle and bone. It is remarkable that a conclusion had not been crystallized concerning atrophy of disuse when applied to the kidney. Indeed, the subject seems to have been unnoticed until Hinman applied it as the basis for his theory of renal counterbalance.

According to this theory, a kidney, after sustaining a temporary injury, as, for example, a temporary period of ureteral obstruction causing hydronephrosis, will go on to complete or almost complete atrophy if allowed to function in competition with its hypertrophic mate. Thus, if the ureter of a kidney is obstructed for two or three weeks, this kidney becomes hydronephrotic and its mate undergoes hypertrophy. If at the end of this time the obstruction to the ureter is relieved, the hydronephrotic kidney supposedly will be placed at a distinct disadvantage. According to the theory of renal counterbalance, the kidneys enter into functional competition and the weaker kidney eventually goes on to complete or almost complete atrophy. In the words of Hinman:

"The healthier side will gradually undergo a compensatory hypertrophy which may be so capable of counterbalance as to render the work of its weak assistant unnecessary, disuse atrophy of which will progressively occur. The reapportionment of functional activity after the alteration occurs by a competitive type of anatomic compensation."

He also stated:

"An animal cannot live after opposite nephrectomy, with a repair hydronephrosis of longer than from two to three weeks. Any repair hydronephrosis, even of

* Submitted for publication, May 21, 1929.

1. Hinman, F.: Renal Counterbalance: An Experimental and Clinical Study with Reference to the Significance of Disuse Atrophy, *Tr. Am. Ass. Genito-Urin. Surg.* 15:241, 1922; Renal Counterbalance, *Arch. Surg.* 12:1105 (June) 1926.

two weeks, will usually eventuate in complete atrophy if the opposite kidney remains healthy and undisturbed. . . ."

The experiments quoted by Hinman on which this theory is based, although numerous and variegated, are somewhat inconclusive. The following two experiments are taken from Hinman's monograph and seem to have the most direct bearing on the subject. The author stated that he has carried out similar experiments, but unfortunately they were not completely reported in his publication.

"Experiment 5.—Late atrophy of hydronephrotic repair; ureteral obstruction of twenty-one days; repair period of 249 days.

"Dog 5, weighing 20 pounds (9 Kg.).

"There was a complete obstruction of the left ureter for twenty-one days. After a ureterocystoneostomy, and a drainage period of 249 days, the urine was free from bacteria and pus. The dog was killed, under ether, with preliminary functional study. The appearance time of phenolsulphonphthalein was four minutes for the right kidney, and eight minutes for the left. In the first fifteen minutes, 25 per cent of the dye was excreted by the right kidney, and 5 per cent by the left; in the second fifteen minutes, 20 per cent by the right kidney and 2.5 per cent by the left, the total excretion for the first half-hour being 45 per cent for the right kidney and 7.5 per cent for the left. At necropsy, the left kidney weighed 15 Gm.; the right, 48 Gm. The ureter was freely patent. There was no pelvic dilatation on section and no evidence of infection. [An illustration] shows that the left kidney was reduced to one third its size, and that, even in the gross, cortical atrophy was quite marked."

"Experiment 8.—Thirty days left hydronephrosis; left ureterocystoneostomy; seven days later, partial obstruction of right ureter. Killed in 390 days.

"Dog 8, a male shepherd, weighing 42 pounds (19.1 Kg.).

"Nov. 1, 1920, ligation of left ureter.

"Blood urea nitrogen, 18 mg. per hundred cubic centimeters; nonprotein nitrogen, 34 mg. per hundred cubic centimeters; phenolsulphonphthalein, 70 per cent in two hours. . . .

"December 2, left ureterocystoneostomy.

"December 9, partial ligation of right ureter. Under ether anesthesia and surgical asepsis, the abdomen was opened in the midline just below the umbilicus.

" . . . The right ureter was identified in its bed as low down as possible without disturbing the recent operative area behind the bladder. A short length of ureter was freed in an area about 3 cm. from its point of entry into the bladder, and a rubber band 2 mm. wide was placed around it and stretched. The ends of the band thus stretched were tied with silk so as to form a moderate constriction of the ureter. . . . The animal recovered slowly from the operation. . . . A month after operation, he seemed quite normal and ate normal amounts.

"Nov. 29, 1921, . . . urea nitrogen, 26 mg. per hundred cubic centimeters; nonprotein nitrogen, 49 mg. per hundred cubic centimeters, and creatinine, 1.93 mg. per hundred cubic centimeters.

"Jan. 4, 1922, killed. Necropsy: The dog was in excellent condition; the weight was 42.5 pounds (19.3 Kg.). . . . The animal had been passing well formed stools and clear urine. Phenolsulphonphthalein, the first hour, was 53 per cent;

the second hour, 20 per cent. Blood urea nitrogen was 21 mg. per hundred cubic centimeters; nonprotein nitrogen, 41 mg. per hundred cubic centimeters. The dog was killed with ether.

" . . . The abdominal organs, except for the genito-urinary tract, presented no lesions whatever. The heart was not enlarged and showed no pathologic alterations. The lungs were clear. A sample of urine from the right ureter was clear and showed a considerable amount of pigment. The urine from the left ureter was cloudy. It showed an equal amount of pigment. . . .

"The left kidney was normal in shape and slightly enlarged. It collapsed readily at the hilum with pressure, showing a slight degree of hydronephrosis. The ureter of the kidney was very large, being 1 cm. in diameter. It was not tortuous. Its opening lay in the midline of the bladder posteriorly and was fully patent. . . . The right kidney was very large and had a very thin wall. There was a crescentic nodule of parenchyma at its upper pole $1\frac{1}{2}$ cm. thick and 7 cm. long. In all other areas, the wall was of paper thinness. The ureter was slightly larger than that of the opposite side. It was 1.3 cm. in diameter. It was much thinner than the left ureter and very tortuous. Near the bladder, it presented an obstructed area, at which point the rubber band, placed Dec. 9, 1920, was localized. Beyond this, it was of normal diameter. The right ureterovesical orifice through which this ureter opened was normal in all respects. . . . Gentle pressure on the hydronephrotic sac caused a flow of fluid through this ureteral orifice. The wall of the bladder was normal in appearance. . . . The respective sizes and weights of the two kidneys were as follows:

	Length (Pole to Pole)	Width (Side to Side)	Depth (Hilum to Greater Curve)	Weight	Pelvic Capacity
Left kidney....	6.95 cm.	2.5 cm.	3.0 cm.	47 gm.	5 cc.
Right kidney...	16.00 cm.	8.0 cm.	7.5 cm.	52 gm. (empty)	400 cc.

"The nitrogen content of the urine from the left kidney was: urea nitrogen 0.0045 Gm. in 1 cc.; nonprotein nitrogen, 0.0065 Gm. in 1 cc. The nitrogen content of the urine from the right kidney was: urea nitrogen, 0.0039 Gm. in 1 cc.; nonprotein nitrogen, 0.0068 Gm. in 1 cc."

In the first of the foregoing experiments, a kidney injured by a complete ureteral obstruction lasting twenty-one days has in a period of repair of two hundred and forty-nine days become an organ weighing 15 Gm., which is about one-third the weight of its hypertrophic mate. Although the excretion of phenolsulphonphthalein was only 7.5 per cent in one-half hour, still, the experiment can hardly be considered as one in which the injured kidney has gone on to complete atrophy. Whether this kidney would have become completely atrophied after a longer period of competition, it is impossible to say. Our experiments do not indicate that this would have occurred. The second experiment shows that a markedly damaged hydronephrotic kidney possesses a remarkable power to undergo repair and hypertrophy if the functional demand is placed on it.

Should the theory of renal counterbalance become established, its clinical application would be of far-reaching importance. It would play a rôle in many types of renal surgery, for if the injury to one kidney

were continued over a sufficiently long period of time to allow the opposite kidney to become fully hypertrophied, the injured kidney would eventually go on to complete atrophy even though the injurious agent were removed. It would be useless, therefore, to carry out plastic operation on a hydronephrotic kidney if its mate had become fully hypertrophied. The plastic operation would have to be supplanted by a removal of the hydronephrotic kidney, since any operation for the relief of an obstruction would be useless so far as restoration of function in that kidney would be concerned. The theory would find application also in cases of unilateral stone in which there was destruction of parenchyma in the involved kidney and accompanying hypertrophy in its mate. The operation of pyelotomy or nephrotomy would be supplanted here by nephrectomy. Also in the treatment of bilateral nephrolithiasis the period of time between the operations for the removal of the stones from each kidney should not be long enough to allow one kidney to undergo hypertrophy.

EXPERIMENTAL TECHNIC

The experiments reported in this paper were conducted on healthy dogs and were of three types. A kidney (in our experiments always the right) was damaged by producing a complete obstruction of its ureter. The obstruction was temporary and its duration varied from twelve to nineteen days. In one group of experiments the animals were killed at the end of the period of obstruction so that the changes in the obstructed and nonobstructed kidneys could be studied. In all the other experiments, the right ureter was implanted into the bladder after the temporary period of obstruction. In one group of these experiments the hypertrophied mate was removed several days after the obstruction was relieved, while in another group the hypertrophied kidney was allowed to remain undisturbed.

In all the experiments, observations of the gross and of the histologic changes in the kidneys were made. Only those experiments are reported in which there was no evidence of renal infection or in which there was simply a mild degree of pyelonephritis. In practically all the experiments, preoperative and postoperative studies of the blood urea were made.

Each operation was carried out under strictly aseptic precautions. Open ether anesthesia was used, preceded by a subcutaneous injection of 0.015 Gm. of morphine. The operative procedures are described in detail in the following paragraphs, and to avoid repetition will be referred to in the protocols only by name.

Ligation of Ureter.—The abdomen was opened through a suprapubic midline incision about 4 cm. long. The bladder was brought into the wound, and the right ureter was isolated close to the bladder. Here the ureter was doubly ligated with silk and cut between ligatures. The structures were replaced in the abdominal cavity, and the wound was closed in layers with silk.

Implantation of the Ureter into the Bladder.—The hydronephrosis was relieved in each experiment by implanting the ureter into the bladder. The abdomen was opened through a right rectus incision. The bladder was elevated into the wound, and the proximal end of the ureter was isolated. It was dissected free for about 2 cm.; its ligated end was excised, and, after allowing the urine to drain off, the end of the ureter was split longitudinally for about 0.5 cm. A suture of fine

catgut was placed in each end of the split ureter. An incision about 6 mm. long was made through the posterior wall of the bladder, and through this opening the ends of the ureter were inserted. The split ends of the ureter were then separated in opposite directions and the sutures of catgut were completed by passing each end through the wall of the bladder and were tied. The incision in the wall of the bladder was closed around the ureter and one or two sutures were passed between the bladder and the adventitia of the ureter. Care was taken to avoid obstruction at the new ureteral orifice. The structures were replaced in the abdominal cavity and the wound was closed in layers with silk.

Nephrectomy.—The left kidney was removed through either a left rectus or a left lumbar incision. The kidney was freed and delivered; the ureter and renal vessels were doubly ligated and cut between ligatures. The wound was approximated in layers with silk.

EFFECTS ON KIDNEYS OF THIRTEEN TO SIXTEEN DAY PERIODS OF UNILATERAL COMPLETE URETERAL OBSTRUCTION

PROTOCOL 1.—In dog A 51, a male mongrel, weighing 17.9 Kg., hydronephrosis was produced for sixteen days.

Sept. 23, 1927: The right ureter was ligated.

October 9: The dog was killed to obtain specimens of the kidneys after sixteen days of complete ureteral obstruction. The results of the general necropsy were negative. The right kidney showed a marked degree of hydronephrosis and dilatation of the ureter. The left kidney showed compensatory hypertrophy. The weights and measurements of the kidneys were:

	Right	Left
Weight	59.0 Gm.	76.8 Gm.
Length	7.5 cm.	7.5 cm.
Transverse diameter.....	4.9 cm.	5.2 cm.
Anteroposterior diameter.....	2.8 cm.	3.6 cm.
Capacity of pelvis.....	43.0 cc.	3.5 cc.
Cortex	7.0 mm.	10.0 mm.

The appearance of the kidneys is shown in figure 1. The pyelogram of the right kidney (fig. 2) showed a marked dilatation of the pelvis, calices and ureter, and a definite thinning of the parenchyma. The pyelogram of the left kidney was normal.

Histologic Observations.—In the left kidney, there was a diffuse hyperemia, particularly of the glomeruli which appeared very large, with occasional collections of serum precipitate in the capsular spaces.

In the right kidney, the glomeruli appeared concentrated in comparison to their distribution in the left kidney. The glomerular tufts showed no pathologic change, but occasionally there were small amounts of serum precipitate in the capsular spaces. There were patchy areas of tubular dilatation and widespread tubular atrophy. The tubular dilatation was most marked in the superficial zone of the cortex which was also the seat of interstitial fibrosis.

PROTOCOL 2.—In dog A 52, a white female mongrel, weighing 12.4 Kg., hydronephrosis was produced for fourteen days.

Sept. 29, 1927: The right ureter was ligated.

October 13: The dog was killed to obtain specimens of the kidneys after fourteen days of complete ureteral obstruction. The results of the general

necropsy were negative. The right kidney was hydronephrotic, and its ureter was dilated. The left kidney showed compensatory hypertrophy. The weights and measurements of the kidneys were:

	Right	Left
Weight	55.4 Gm.	56.0 Gm.
Length	8.0 cm.	7.2 cm.
Transverse diameter.....	4.5 cm.	4.6 cm.
Anteroposterior diameter.....	3.2 cm.	2.8 cm.
Capacity of pelvis.....	20.0 cc.	...
Cortex	7.0 mm.	8.0 mm.

Fig. 1.—Appearance of kidneys after complete obstruction of the right ureter for sixteen, fourteen, thirteen and thirteen days, respectively, showing the marked damage (table 1).

The pyclogram of the right kidney (fig. 2) showed a moderate dilatation of the ureter and a marked dilatation of the pelvis and calices. The pyclogram of the left kidney was normal.

Histologic Observations.—The glomeruli in the left kidney were large, and occasional collections of serum precipitate were observed in the capsular spaces. The tubules showed no pathologic change. There was marked hyperemia of both cortex and medulla.

The glomeruli in the right kidney were uniformly small and in many of them there was partial or complete necrosis of the tufts (fig. 3). The necrotic portions

had a granular basophilic appearance with fragmentation and pyknosis of nuclei. In some instances, only a small fragment of the tuft was left intact and the capsular space contained a large amount of granular debris. There was widespread collapse and atrophy of tubules, which was particularly prominent in the superficial zone of the cortex. There was some slight diffuse increase of interstitial connective tissue.

PROTOCOL 3.—In dog A 53, a male mongrel, weighing 12.7 Kg., hydronephrosis was produced for fourteen days.

Sept. 29, 1927: The right ureter was ligated.

Fig. 2.—Pyclograms of kidneys after complete obstruction of the right ureter for sixteen, fourteen, thirteen and thirteen days, respectively.

October 13: The dog was killed to obtain specimens of the kidneys after a period of fourteen days of complete ureteral obstruction. The results of the general necropsy were essentially negative. The right kidney was distinctly hydronephrotic with dilatation of the ureter. Its urine showed no evidence of infection. The left kidney appeared to be hypertrophic. The weights and measurements of the kidneys were:

	Right	Left
Weight	31.4 Gm.	47.0 Gm.
Length	6.7 cm.	6.4 cm.
Transverse diameter.....	3.8 cm.	5.0 cm.
Anteroposterior diameter..	2.4 cm.	2.9 cm.
Cortex	4.0 mm.	7.0 mm.

The appearance of the kidneys is shown in figure 1.

Fig. 3.—Cortex of right kidney of dog A 52, protocol 2, showing necrosis of a portion of a glomerular tuft; $\times 65$.

Fig. 4.—Cortex of right kidney of dog A 53, protocol 3, showing a partially necrotic glomerular tuft and many atrophic, collapsed tubules. There is a diffuse increase in interstitial fibrous connective tissue and dilatation of the loops of Henle; $\times 65$.

Histologic Observations.—The glomeruli in the left kidney appeared larger than normal, and the tufts were distended with red blood cells. Many glomeruli showed collections of serum precipitate in the capsular spaces. The tubules appeared normal except for swelling and granularity of the epithelium. The interstitial tissue was moderately edematous. Both cortex and medulla were hyperemic.

In comparison to the left kidney, there appeared to be a concentration of glomeruli in the right kidney, especially in the superficial zone of the cortex. Some of the glomeruli appeared normal, but a great many manifested varying degrees of degenerative changes ranging from pyknosis of a few nuclei to necrosis of the entire tuft (fig. 4). There was marked tubular atrophy, many of the tubules being represented only by a small solid group of epithelial cells surrounded by a basement membrane. Occasional dilated tubules were seen. There was diffuse increase of interstitial fibrous connective tissue which was most pronounced in the medulla and in the cortex corticis.

PROTOCOL 4.—In dog A 54, a young male hound, weighing 9.8 Kg., hydronephrosis was produced for thirteen days.

Sept. 30, 1927: The right ureter was ligated.

October 13: The dog was killed to obtain specimens of the kidneys after a period of thirteen days of complete ureteral obstruction. The results of the general necropsy were negative. The right kidney was large and hydronephrotic and the ureter was dilated. The urine from this kidney showed no evidence of infection. The left kidney appeared to be normal but somewhat hypertrophic. The weights and measurements of the kidneys were:

	Right	Left
Weight	48.5 Gm.	61.8 Gm.
Length	7.5 cm.	6.8 cm.
Transverse diameter.....	4.8 cm.	5.0 cm.
Anteroposterior diameter.....	2.0 cm.	2.7 cm.
Cortex	3.5 mm.	6.0 mm.
Capacity of pelvis.....	80.0 cc.	...

The appearance of the kidneys is shown in figure 1. The pyelogram of the right kidney (fig. 2) showed a very marked degree of hydronephrosis with a thin parenchyma. The pyelogram of the left kidney was normal.

Histologic Observations.—The glomeruli in the left kidney were large and the tufts hyperemic and usually completely filled the capsular spaces. The capsules occasionally contained a small amount of serum precipitate. There was moderate parenchymatous degeneration of the tubular epithelium. Both cortex and medulla were intensely hyperemic, and the tubules were widely separated by distended capillaries and edematous interstitial connective tissue.

The changes in the right kidney were essentially the same as those in the right kidney of dog A 53 (protocol 3), except that there was more widespread degeneration of glomeruli and many glomeruli with normal appearing tufts showed proliferation of capsular epithelium. The pyramids were the seat of pronounced tubular atrophy and fibrosis.

PROTOCOL 5.—In dog A 55, a young female hound, weighing 8.7 Kg., hydronephrosis was produced for thirteen days.

Sept. 30, 1927: The right ureter was ligated.

October 13: The dog was killed for specimens of the kidneys after a period of thirteen days of complete ureteral obstruction. The results of the general necropsy were negative. The right kidney was markedly hydronephrotic, and its ureter was dilated. The urine showed no evidence of infection. The left kidney

was darker and more congested than the right and appeared to be hypertrophic. The weights and measurements of the kidneys were:

	Right	Left
Weight	45.0 Gm	46.0 Gm
Length	8.2 cm	6.6 cm
Transverse diameter.	4.8 cm	3.4 cm.
Anteroposterior diameter.	2.4 cm	2.6 cm.
Cortex	5.0 mm	8.0 mm
Capacity of pelvis.	50.0 cc	.

The appearance of the kidneys is shown in figure 1. The pyelogram of the right kidney (fig. 2) showed a marked degree of hydronephrosis. The pyelogram of the left kidney was normal.

Histologic Observations.—Left Kidney: The glomeruli were large, and the tufts were plump and in most instances filled their capsules. Occasional glomeruli showed partial necrosis of the tuft, manifested by loss of nuclei with granular degeneration of the cytoplasm. There was a moderately severe parenchymatous degeneration of the tubular epithelium. The interstitial tissue was edematous and hyperemic.

TABLE 1—Data on Dogs Following Unilateral Complete Ureteral Obstruction

Protocol	Duration of Complete Obstruction of Right Ureter, Days	Weight of Kidneys, Gm		Percentage of Total Renal Mass	
		Right	Left	Right	Left
1 (Dog A 51)	16	59.0	76.8	43.4	56.6
2 (Dog A 52)...	14	55.4	58.0	49.7	50.3
3 (Dog A 53)...	14	31.4	47.0	40.0	60.0
4 (Dog A 54)...	13	48.5	61.8	43.9	56.1
5 (Dog A 55)...	13	45.0	46.0	49.5	50.5

In the right kidney, there was a concentration of glomeruli in the subcapsular zones of the cortex and many of them were partially or completely necrotic. The tubules were predominantly atrophic although a few distended loops were seen. Parenchymatous degeneration of tubular epithelium was present. In general, the sections appeared very similar to those from the right kidneys of dogs A 53 and A 54 (protocols 3 and 4).

These five experiments are recorded to show the effects on the kidneys of periods of from thirteen to sixteen days of unilateral complete ureteral obstruction. It can be seen from the descriptions and illustrations (figs. 1 and 2) that a fairly marked degree of hydronephrosis and renal damage was produced by the ureteral obstruction. The relatively slight differences in weight between the hydronephrotic right kidney and the hypertrophic left kidney are striking and especially interesting when compared with the relative weights of the kidneys of some of the other experiments.

A summary of the histologic changes observed in this group of experiments follows:

The undisturbed left kidneys of these animals were fairly uniform in their histologic appearances. Both cortex and medulla were intensely

hyperemic with considerable interstitial edema, particularly of the cortex. The glomeruli were large, and the hyperemic tufts tended to fill their capsular spaces. The presence of serum precipitate within the glomerular capsule was a common occurrence.

The obstructed right kidneys showed considerable variation in the extent of the pathologic changes. The earliest change was manifested in the tubules and interstitial tissue (fig. 4). Dilatation as well as atrophy and collapse of tubules, with interstitial edema, was seen in kidneys showing no glomerular damage. The extent of tubular atrophy varied but was most marked in those kidneys showing glomerular damage. The glomerular changes consisted of partial or complete necrosis of the tufts (figs. 3 and 4). The number of tufts damaged varied in different animals but in none of them did the damaged tufts outnumber those that appeared normal. The necrosis manifested itself by a basophilic, granular degeneration of the cytoplasm with pyknosis, fragmentation, and disappearance of nuclei. Occasional masses of granular cellular debris were present in the capsular spaces around necrotic tufts. In one animal there was moderate proliferation of the capsular epithelium. There was a diffuse increase in interstitial fibrous connective tissue, most pronounced in the medulla and in the subcapsular zone of the cortex. In the fibrosed outer zone of the cortex proper the glomeruli appeared especially numerous, and it was in these concentrated glomeruli that the most severe damage was manifest.

REPAIR OF HYDRONEPHROTIC KIDNEYS WITH REMOVAL OF HYPERTROPHIC MATE

Protocol 6.—In dog A 20, a female collie, weighing 14 Kg., hydronephrosis was produced for eleven days followed by a period of repair of eight hundred and twenty-eight days.

Jan. 9, 1925: The blood urea was 38 mg. per hundred cubic centimeters.

January 13: The blood urea was 23 mg. The right ureter was ligated

On January 15, the blood urea was 14.1 mg.; on January 22, 50.1 mg.

January 24: The right ureter was implanted into the bladder after a period of eleven days of complete ureteral obstruction.

January 26: The blood urea was 33 mg. Left nephrectomy was performed. The left kidney appeared to be grossly normal although it was somewhat hypertrophied. The weight and measurements were: weight, 34.5 Gm.; length, 6 cm.; transverse diameter, 3.8 cm.; anteroposterior diameter, 2.8 cm.; cortex, 7 mm.

February 3: The blood urea was 140.4 mg., but in spite of this the dog appeared to be in good general condition.

On February 9, the blood urea was 112.3 mg.; February 13, 102 mg.; February 26, 69 mg.; March 16, 40.2 mg.; March 25, 66.8 mg.; April 1, 53.5 mg.; April 10, 53.5 mg.; May 7, 62.5 mg.; June 25, 27 mg.; July 22, 43.2 mg. (condition excellent); September 24, 44 mg.; October 16, 37 mg.; November 13, 42 mg.; December 23, 80 mg.

Jan. 4, 1926: The dog gave birth to a litter of seven pups.

January 14: Her general condition was excellent. The blood urea was 68.5 mg.

On February 13, the blood urea was 44.5 mg.; March 17, 57.8 mg.; June 24, 68.4 mg.; August 17, 37 mg.

September 1: The dog gave birth to a litter of seven pups.

On October 13, the blood urea was 32 mg.; November 19, 53 mg.

December 23: The microscopic examination of the urine showed no pus cells, red blood cells or casts.

On Jan. 24, 1927, the blood urea was 54 mg.; March 4, 41 mg.; April 26, 36 mg.

Fig. 5.—Pyelograms of the obstructed right kidneys of dogs A 20, A 40, A 24, A 38 and A 48, showing a tendency of the pelvis to return to normal shape and size.

May 2: For the past few days the dog appeared sick, and on this date she was found dead in the kennels.

Necropsy.—There were no external signs of violence. The heart was normal. The lungs showed some small patches of pneumonia. On opening the abdominal cavity, about 100 cc. of dark fluid was found. All the abdominal organs except the pancreas and kidneys were normal. The former showed definite gross and microscopic evidence of an acute pancreatitis. The left kidney had been removed at a previous operation. The right kidney appeared to be hypertrophic. Its ureter was slightly dilated at its upper portion for a distance of about 4 cm. but below this it was normal. The anastomosis of the ureter into the bladder was satisfactory and appeared to be perfectly patent. The bladder was normal. The weight and measurements of the right kidney were: weight, 582 Gm.; length, 7.5 cm.; transverse diameter, 5 cm.; anteroposterior diameter, 3 cm.; capacity of pelvis,

5.9 cc.; cortex, 4 mm. A pyelogram showed a slight degree of dilatation of the upper portion of the ureter and the pelvis, but was otherwise not remarkable except that a small amount of the sodium iodide had extravasated into the parenchyma in the region of the lower pole (fig. 5). The gross appearance of the kidneys is shown in figure 6.

Histologic Observations.—The glomeruli in the left kidney appeared large with plump, hyperemic tufts which filled their capsules completely. There was a moderate degree of parenchymatous degeneration of the tubular epithelium. Otherwise, there was no pathologic change.

The histologic examination of the right kidney was rendered somewhat unsatisfactory by the amount of postmortem change present. The glomeruli were very large and hypertrophic, with plump cellular tufts which filled their capsules. The usual difference in size between peripheral and central glomeruli was not present and those in the outer zone of the cortex were as large as those in the corticomedullary zone. A few thickened capsules were seen. There was a mild, patchy chronic pyelonephritis, and in the densely infiltrated radial scars the glomeruli were fibrosed and atrophic and the tubules filled with pus cells.

PROTOCOL 7.—In dog A 33, a white and brown female mongrel, weighing 7 Kg., hydronephrosis was produced for fifteen days, followed by a period of repair of five hundred and five days.

On May 18, 1925, the blood urea was 25.5 mg. per hundred cubic centimeters, and on May 25, 47 mg.

May 25: The right ureter was ligated.

On May 27, the blood urea was 49 mg.; on June 9, 33 mg.

June 9: The ureter was implanted into the bladder after a period of fifteen days of complete ureteral obstruction.

June 11: The blood urea was 25 mg. Left nephrectomy was performed. The left kidney appeared grossly normal. The weight and measurements were: weight, 38 Gm.; length, 5.1 cm.; transverse diameter, 3.6 cm.; anteroposterior diameter, 2.5 cm.; cortex, 6 mm.

On June 15, the blood urea was 174.4 mg., but the general condition of the dog seems good. On June 24, it was 80 mg.; on July 8, 76.9 mg.

July 30: The dog gave birth to a litter of five pups.

On September 24, the blood urea was 24 mg.; November 13, 52 mg.; Feb. 13, 1926, 87.7 mg.; March 17, 67.6 mg.; April 29, 65.3 mg.; June 3, 70.2 mg.; June 24, 67.6 mg.; August 16, 23 mg.; October 13, 37 mg.

October 27: The dog was killed in a fight.

Necropsy: The dog sustained extensive wounds of the thoracic wall and right lumbar region. Through the lumbar wound the right kidney had been somewhat lacerated. Aside from these wounds, the results of the necropsy were negative. The right kidney, aside from its lacerations, appeared to be normal. It was firm on palpation and the cut surface showed a normal medulla and cortex. The pelvis and ureter were not dilated. The implantation of the ureter into the bladder was satisfactory and appeared to be perfectly patent. The weight was 32 Gm., and the cortex measured 6 mm.

The gross appearance of the kidneys is shown in figure 6.

Histologic Observations.—In the left kidney, there was diffuse hyperemia and the glomerular tufts were plump, filling their capsules. The tubular epithelium was the seat of moderate parenchymatous degeneration.

Fig. 6.—Appearance of kidneys of experiments of group II, showing the repair and hypertrophy which the hydronephrotic right kidney undergoes after removal of its mate (table 2).

In the right kidney, most of the glomeruli were large and hypertrophic, and there was a collection of serum precipitate within the capsules of many of them. Occasional small fibrosed glomeruli with thickened capsules were encountered. There was no evidence of interstitial fibrosis. The normal architecture was preserved.

PROTOCOL 8.—In dog A 40, a male mongrel, weighing 10.3 Kg., hydronephrosis was produced for fifteen days, followed by a period of repair of two hundred and ninety-three days.

On May 18, 1925, the blood urea was 25.5 mg. per hundred cubic centimeters.

May 25, 1925: The right ureter was ligated. On May 27, the blood urea was 51 mg.; on June 9, 34 mg.

June 9: The ureter was implanted into the bladder after fifteen days of complete ureteral obstruction.

June 11: The blood urea was 31.2 mg.

June 11: Left nephrectomy was performed. The left kidney appeared somewhat hypertrophied but otherwise normal. The weight and measurements were: weight, 36.7 Gm.; length, 6 cm.; transverse diameter, 3.8 cm.; anteroposterior diameter, 2.6 cm.; cortex, 5 mm.

On June 15, the blood urea was 144 mg., but the animal's general condition seems to be good. On June 24, it was 59 mg.; July 8, 54 mg. (weight, 9.3 Kg.); July 31, 59.1 mg.; August 13, 51 mg.; September 24, 48 mg.; October 16, 45 mg.; November 13, 43 mg.; December 23, 50 mg.; Jan. 14, 1926, 52 mg.; February 13, 29.5 mg.; March 17, 47 mg.

March 29: The dog was killed.

Necropsy.—The results of necropsy were negative except the changes found in the urinary tract. The right kidney appeared to be normal and somewhat hypertrophied. The right ureter was slightly dilated. The implantation of the ureter into the bladder was satisfactory and perfectly patent. The weight and measurements of the right kidney were: weight, 40.6 Gm.; length, 6.4 cm.; transverse diameter, 3.8 cm.; anteroposterior diameter, 2.5 cm.; cortex, 5 mm.; capacity of pelvis, 4 cc. A pyelogram appeared relatively normal except for the slight dilatation of the ureter and pelvis (fig. 5). The gross appearance of the kidneys is shown in figure 6.

Histologic Observations.—Except for the general glomerular hypertrophy and the presence of occasional fibrosed, atrophic glomeruli with thickened capsules in the right kidney there was no histologic difference in the two kidneys of this animal. There was no scarring or increase in interstitial fibrous connective tissue.

PROTOCOL 9.—In dog A 24, a brown and white, short haired, male mongrel, weighing 9 Kg., hydronephrosis was produced for twelve days followed by a period of repair of one hundred and fifty-five days.

On Jan. 22, 1925, the blood urea was 43 mg.; on January 27, 27 mg.

January 30: The right ureter was ligated.

On February 3, the blood urea was 32 mg.; on February 9, 44 mg.

February 11: The right ureter was implanted into the bladder after a period of twelve days of complete ureteral obstruction.

February 13: The blood urea was 43 mg.

February 13: Left nephrectomy was performed. The kidney appeared somewhat hypertrophied but otherwise normal. The weight and measurements were: weight, 30.9 Gm.; length, 6 cm.; transverse diameter, 3.7 cm.; anteroposterior diameter, 2.9 cm.; cortex, 6 mm.

On February 16, the blood urea was 85.1 mg.; February 26, 47 mg.; March 9, 24.9 mg.; March 25, 40.2 mg.; April 1, 40.2 mg.

April 10: The dog had been losing weight and had mange. On this date it weighed 6.5 Kg. The blood urea was 43.2 mg.

April 16: The dog's condition seemed better. The blood urea was 24 mg.

May 7: The blood urea was 46 mg.

June 25: The dog was in good condition. The blood urea was 33 mg.

July 14: The dog was killed.

Necropsy.—No abnormalities were found in any of the organs except those of the urinary tract. The right kidney was grossly normal except that it appeared somewhat hypertrophied. The implantation of the ureter into the bladder was satisfactory and perfectly patent. The right ureter and pelvis appeared to be normal. The weight and measurements of the kidney were: weight, 34.1 Gm.; length, 6.1 cm.; transverse diameter, 3.6 cm.; anteroposterior diameter, 2.6 cm.; cortex, 5 mm.; capacity of pelvis, 3.5 cc. A pyelogram showed no abnormalities (fig. 5). The appearance of the kidneys is shown in figure 6.

Histologic Observations.—In the left kidney, the glomeruli were plump and hyperemic, and occasional collections of serum precipitate were present in the capsular spaces.

In the right kidney, there was no evidence of interstitial fibrosis in the cortex. The glomeruli appeared normal except for serum precipitate in the glomerular spaces. The arcuate arteries showed a zone of peri-arterial fibrosis. There was a moderate diffuse increase of fibrous connective tissue in the pyramids.

Protocol 10.—In dog A 38, a black and white female mongrel, weighing 16 Kg., hydronephrosis was produced for sixteen days followed by a period of repair of seventy-nine days.

May 18, 1925: The blood urea was 43.3 mg. per hundred cubic centimeters.

May 20: The right ureter was ligated.

On May 25, the blood urea was 54.5 mg.; on June 3, 47 mg.

June 5: The right ureter was implanted into the bladder after a period of sixteen days of complete ureteral obstruction.

June 8: The blood urea was 43.2 mg.

June 8: Left nephrectomy was performed. The kidney appeared hypertrophied but was otherwise normal. The weight and measurements were: weight, 45.1 Gm.; length, 6.6 cm.; transverse diameter, 3.8 cm.; anteroposterior diameter, 2.7 cm.; cortex, 7 mm.

On June 15, the blood urea was 161 mg.; June 24, 76 mg.; July 8, 62.4 mg.

July 31: The animal's condition was poor. She appeared thin, weak and mangy. The blood urea was 108 mg.

August 13: The dog's general condition seemed much better. The blood urea was 122.1 mg.

August 23: The animal was found dead in the kennels.

Necropsy.—No definite cause of death was found. All the organs seemed normal. The weight and measurements of the right kidney were: weight, 44.5 Gm.; length, 6.2 cm.; transverse diameter, 3.8 cm.; anteroposterior diameter, 2.7 cm.; cortex, 4 mm. The anastomosis of the ureter into the bladder was perfectly patent. The ureter and pelvis were somewhat dilated. A pyelogram was made which, aside from some dilatation of the ureter and pelvis, was relatively normal (fig. 5). The gross appearance of the kidneys is shown in figure 6.

Histologic Observations.—The glomeruli of the left kidney were hyperemic, and many of them contained serum precipitate within the capsular spaces.

The glomeruli of the right kidney were larger than in the left kidney. There was a moderate amount of scarring in the pyramids; otherwise the two kidneys were histologically identical.

PROTOCOL 11.—In dog A 30, a brown and white male mongrel, weighing 6.9 Kg., hydronephrosis was produced for sixteen days followed by a period of repair of forty-two days.

May 18, 1925: The blood urea was 25 mg. per hundred cubic centimeters.

May 19: The right ureter was ligated.

On May 21, the blood urea was 26.7 mg.; May 25, 51 mg.; June 3, 56 mg.

Fig. 7.—Cortex of right kidney of dog A 30, protocol 11. The right kidney was obstructed sixteen days, and two days following relief of the obstruction the left kidney was removed and the right kidney allowed a forty-two day repair period during which time it was forced to carry the entire renal function. There was no essential difference in the histologic appearance of this kidney as compared with the left; $\times 45$.

June 4: The right ureter was implanted into the bladder after a period of sixteen days of complete ureteral obstruction.

June 6: The blood urea was 23 mg.

June 6: Left nephrectomy was performed. The kidney appeared grossly normal and weighed 27.3 Gm. The measurements were: length, 5.1 cm.; transverse diameter, 3.5 cm.; anteroposterior diameter, 2.5 cm.; cortex, 8 mm.

June 8: The blood urea was 230 mg. per hundred cubic centimeters, but the general condition seemed good in spite of this high elevation.

On June 15, the blood urea was 127 mg.; June 24, 112 mg.; July 8, 72 mg. July 16: The dog was killed.

Necropsy.—The general observations were negative. The right kidney appeared somewhat small, and there was some definite dilatation of the ureter and pelvis still present. The weight and measurements were: weight, 22.3 Gm.; length, 5.5 cm.; transverse diameter, 3.1 cm.; anteroposterior diameter, 21 cm.; capacity of pelvis, 4.5 cc.; cortex, 6 mm. A pyelogram appeared normal except for a slight dilatation of the pelvis and ureter. The appearance of the kidneys is shown in figure 6.

Histologic Observations.—The kidneys showed no histologic abnormality and were identical in appearance except for a mild pyelonephritis and parenchymatous degeneration of tubular epithelium in the right kidney. Figure 7 shows the sub-capsular cortex of the right kidney. There were no atrophic, fibrosed glomeruli in the right kidney, nor was there any interstitial fibrosis.

PROTOCOL 12.—In dog A 48, a short haired, black and tan male mongrel, weighing 11.2 Kg., hydronephrosis was produced for nineteen days followed by a period of repair of thirty-four days.

July 1, 1925: The blood urea was 18.6 mg. per hundred cubic centimeters.

July 1: The right ureter was ligated.

July 20: The blood urea was 25.1 mg.

July 20: The right ureter was implanted into the bladder after a period of nineteen days of complete ureteral obstruction.

July 22: The blood urea was 21 mg.

July 27: Left nephrectomy was performed. The kidney appeared hypertrophied, but was otherwise normal. The weight and measurements were: weight, 47 Gm.; length, 6.6 cm.; transverse diameter, 3.9 cm.; anteroposterior diameter, 3.5 cm.; cortex, 7 mm.

August 4: The blood urea was 187.2 mg. The dog weighed 12.2 Kg.

August 23: The dog died from distemper.

Necropsy.—There were definite areas of consolidation in both lungs, but otherwise the results of the general necropsy were negative. The right kidney appeared somewhat large and showed definite dilatation of the pelvis and ureter. The anastomosis of the ureter into the bladder was patent. The weight measurements were: weight, 42.2 Gm.; length, 6.7 cm.; transverse diameter, 3.9 cm.; anteroposterior diameter, 2.6 cm.; cortex, 5.5 mm.; capacity of pelvis, 14 cc. A pyelogram showed that a fairly marked degree of hydronephrosis was still present (fig. 5). The gross appearance of the kidneys is shown in figure 6.

Histologic Observations.—Except for marked hyperemia there were no pathologic changes in the left kidney. The entire cortex and medulla of the right kidney showed a marked increase of interstitial fibrous connective tissue. This fibrosis did not have an even distribution but was most severe in the medulla and in the outer zones of the cortex with many dense radial scars. The glomeruli were condensed so that a great many were encountered in each field. Most of the glomerular tufts appeared normal as to structure although many of them were very small. They were uniformly hyperemic and in the corticomedullary zone a number of them were hypertrophic with collections of serum precipitate in the capsular spaces. Rarely small fibrosed glomeruli were seen. The tubules were generally very small in diameter, and occasional tubules were seen which were dilated and filled with red blood cells.

In this series of experiments (table 2), the right kidney was rendered hydronephrotic by complete ureteral obstruction for from eleven to nineteen days. Several days after the obstruction was relieved, the hypertrophic mate was removed so that the hydronephrotic kidney had to carry on all of the renal function.

While these experiments have no direct bearing on the question of renal atrophy of disuse, it was necessary to conduct them as control experiments in studying the problem of renal counterbalance, because, if it were demonstrated that an injured kidney did undergo progressive atrophy when allowed to remain in competition with its hypertrophic mate, it would also be essential to demonstrate that a similarly injured kidney could perform the necessary renal function if the entire load were

TABLE 2.—Data on Dogs with Repair of Hydronephrotic Kidney and Removal of Hypertrophic Mate

Protocol	Duration of Complete Obstruction of Right Ureter, Days	Interval Between Relief of Obstruction to Right Ureter and Left Nephrectomy, Days	Period of Repair of Right Kidney, Days	Weight of Kidneys, Gm.	
				Right, at Autopsy	Left, at Operation
6 (Dog A 20).....	11	2	828	58.2	34.5
7 (Dog A 33).....	15	2	505	32.0	38.0
8 (Dog A 40).....	15	2	293	40.6	36.7
9 (Dog A 24).....	12	2	155	34.1	30.9
10 (Dog A 38).....	16	3	79	44.5	45.1
11 (Dog A 30).....	16	2	42	22.3	27.3
12 (Dog A 48).....	19	7	34	42.2	47.0

thrown on it. In this way it could be indicated that the injury which had been applied to the kidney was not of itself sufficient to cause the progressive atrophy and that some other factor was necessary. These experiments show that the hydronephrotic kidney is capable of becoming a functionally good organ, and they are interesting in that they show how well an injured kidney can undergo repair and hypertrophy and carry on the entire renal function when the necessity is placed on it (figs. 5, 6 and 7).

In practically all these experiments the blood urea showed a definite elevation following the removal of the hypertrophic left kidney, but as a general rule this gradually returned to a relatively normal level. Apparently the injured right kidney could not immediately take over the entire load of renal function satisfactorily, but could do so later as it underwent repair and hypertrophy.

Histologically, the left kidneys of these animals were very hyperemic, and the glomerular tufts were plump and completely filled the capsular spaces. Occasional glomeruli contained collections of serum precipitate.

The right kidneys showed unmistakable glomerular hypertrophy which was especially well marked in those animals which were allowed the longest periods of repair after relief of the obstruction.

It would seem from the infrequency of finding damaged glomeruli or tubules even in as short a time as thirty-four days after relief of the obstruction that recovery from the injury is rapid when the entire functional load is placed on the injured kidney. This observation becomes particularly striking when the right kidneys of this series are compared with the right kidneys of series I. The only sign of injury manifested by the right kidneys of series II was diffuse interstitial fibrosis, and in animals having a repair period of forty-two days or more there was no evidence whatsoever of previous renal injury (fig. 7).

REPAIR OF THE HYDRONEPHROTIC KIDNEY WITH THE HYPERTROPHIC MATE UNDISTURBED

PROTOCOL 13.—In dog A, young black, male mongrel, weighing 12.8 Kg., hydronephrosis was produced for twelve days followed by a period of repair of eight hundred and seven days.

March 6, 1925: The preoperative blood urea was 30.5 mg. per hundred cubic centimeters. The right ureter was ligated.

On March 9, the blood urea was 43.2 mg.; March 13, 30.5 mg.; March 16, 18 mg. The dog was in excellent condition.

March 18: The right ureter was implanted into the bladder after a period of twelve days of complete ureteral obstruction.

On March 20, the blood urea was 41.6 mg.; March 25, 34 mg.; April 1, 27.2 mg.; April 16, 30 mg.; April 23, 40.2 mg.; May 7, 50 mg.; June 25, 30 mg.; July 22, 31.9 mg.; September 24, 40 mg.; October 16, 26 mg. (weight 24 Kg.); February 13, 1926, 46.8 mg.; March 17, 44.9 mg.; April 29, 26 mg.; June 3, 29.2 mg.; August 16, 28 mg.; October 13, 30 mg.; November 19, 36 mg.; Jan. 24, 1927, 47 mg.

On January 24, the microscopic examination of the urine was normal. On March 4, the blood urea was 32 mg.; on April 26, 30 mg.

June 3: The dog was first given 0.015 Gm. of morphine subcutaneously, and then 500 cc. of physiologic solution of sodium chloride was given intravenously in order to produce diuresis. With the animal under procaine hydrochloride anesthesia, the ureters were exposed and catheters were inserted into them. One cubic centimeter of phenolsulphonphthalein was given intravenously. On the left side the appearance time was four minutes, and 44 per cent of the dye was excreted in one hour in 20 cc. of urine. On the right side the appearance time was eight minutes, and 14 per cent of the dye was excreted in one hour in 14 cc. of urine. The urine from each kidney was normal. The dog was killed with magnesium sulphate injected intravenously.

Necropsy.—The dog weighed 23.2 Kg. All the organs were normal except the kidneys. The right kidney was about one-half the size of the left, but had the appearance of a functioning organ with a firm parenchyma. The anastomosis between the right ureter and the bladder was patent. The right ureter showed a moderate degree of dilatation, and there was a rather marked degree of dilatation of the extrarenal portion of the pelvis of the right kidney. The left kidney

appeared to be normal and somewhat hypertrophied. The weights and measurements of the kidneys were:

	Right	Left
Weight	40.5 Gm.	71.5 Gm.
Length	6.6 cm.	7.5 cm.
Transverse diameter.....	3.8 cm.	4.5 cm.
Anteroposterior diameter.....	2.2 cm.	2.5 cm.
Capacity of pelvis.....	12.0 cc.	5.0 cc.
Cortex	5.0 mm.	5.5 mm.

The appearance of the kidneys is shown in figure 8. Pyelograms of both kidneys were made (fig. 9). The pyelogram of the right kidney showed a marked dilatation of the extrarenal portion of the pelvis, but the intrarenal portion of the pelvis and the calices appeared to be relatively normal. The pyelogram of the left kidney was normal.

Histologic Observations.—The right and left kidneys were histologically identical except that the glomeruli were uniformly hypertrophic in the right. Occasional fibrosed tufts adherent to thickened capsules were seen in both kidneys, but neither showed any interstitial fibrosis nor any evidence of extensive glomerular or tubular atrophy (fig. 10).

PROTOCOL 14.—In dog A 41, a red and brown female, weighing 8.8 Kg., hydro-nephrosis was produced for sixteen days followed by a period of repair of seven hundred and twenty-eight days.

May 18, 1925: The blood urea was 41.6 mg. per hundred cubic centimeters.

May 19: The right ureter was ligated.

On May 21, the blood urea was 23.5 mg., and on May 25, 35.1 mg.

June 4: The right ureter was implanted into the bladder after a period of sixteen days of complete ureteral obstruction.

On June 6, the blood urea was 29 mg.; June 15, 38.6 mg.; June 24, 35 mg.; July 8, 29.5 mg. (general condition good, weight 8.2 Kg.); July 31, 28.9 mg.; September 24, 20 mg.; October 16, 27 mg.; November 13, 33 mg.; Jan. 14, 1926, 46.8 mg.; March 17, 25.1 mg.; April 29, 22 mg.; June 3, 36.4 mg.; June 24, 44 mg.; August 16, 22 mg.; October 13, 20 mg.; November 19, 27 mg. On December 23, the microscopic examination of urine was normal. On Jan. 24, 1927, the condition of the dog was good, and blood urea was 35 mg. On March 4, it was 22 mg., and on April 26, 24 mg.

June 2: The dog was given 0.015 Gm. of morphine, subcutaneously, and 500 cc. of water was given by stomach tube to produce diuresis. With the animal under procaine hydrochloride anesthesia, both ureters were exposed and catheters were inserted into them. One cubic centimeter of phenolsulphonphthalein was injected intravenously. On the left side the appearance time was four minutes, and 50 per cent of the dye was excreted in one hour in 18 cc. of urine. On the right side the appearance time was fifteen minutes, and 10 per cent of the dye was excreted in 8 cc. of urine in one hour. The urine from each kidney was normal. The dog was killed with ether.

Necropsy.—The dog weighed 13.8 Kg. All the organs were normal except the kidneys. The right kidney was small and somewhat atrophic. The lower pole was somewhat larger than the upper one. The parenchyma was firm and seemed to consist of good renal tissue. The anastomosis between the right ureter and the bladder was patent. The right ureter showed a moderate degree of dilatation, but the kidney itself was not hydronephrotic. The left kidney appeared to be

Fig. 8 A and B.—Appearance of kidneys in experiments of group III. The right ureter had been obstructed for periods varying from twelve to nineteen days following which the obstruction was relieved and the right kidney allowed to function in "competition" with its undisturbed hypertrophic mate. These photographs show that the right kidneys contain a considerable amount of renal tissue and did not undergo atrophy of disuse (table 3).

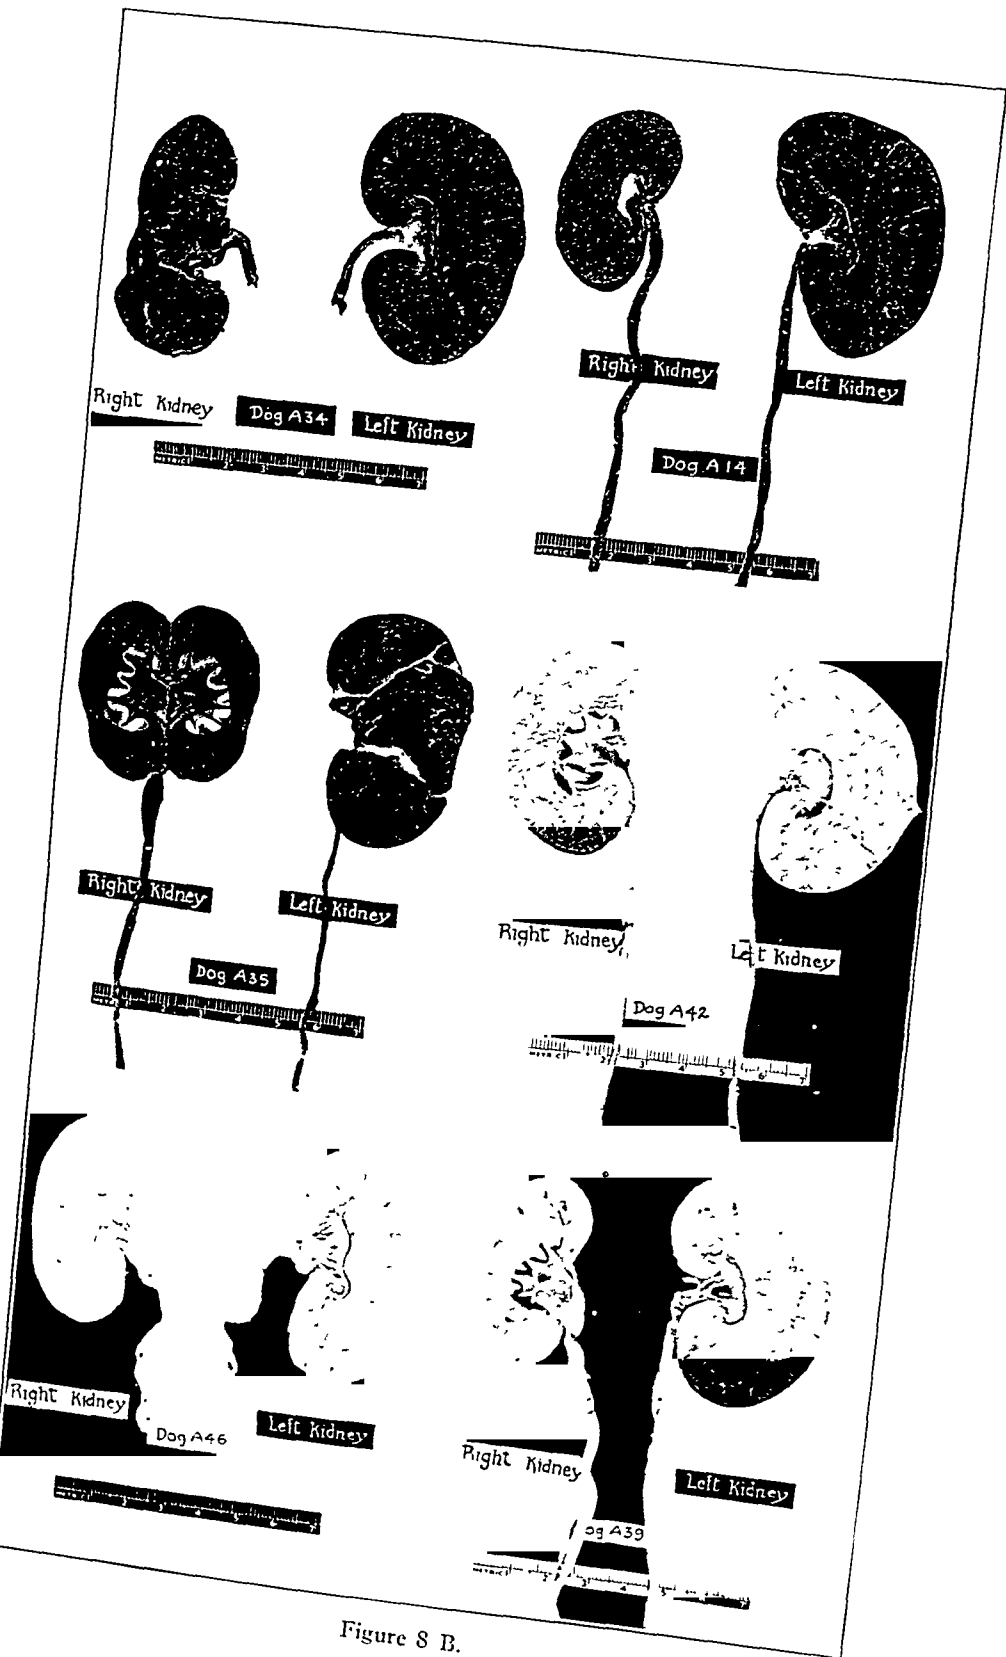

Figure 8 B.

normal and somewhat hypertrophied. The weights and measurements of the kidneys were:

	Right	Left
Weight	16.2 Gm.	48.7 Gm.
Length	5.2 cm.	6.4 cm.
Transverse diameter.....	2.5 cm.	4.1 cm.
Anteroposterior diameter.....	1.9 cm.	3.5 cm.
Capacity of pelvis.....	5.5 cc.	3.5 cc.
Cortex	3.0 mm	6.0 mm

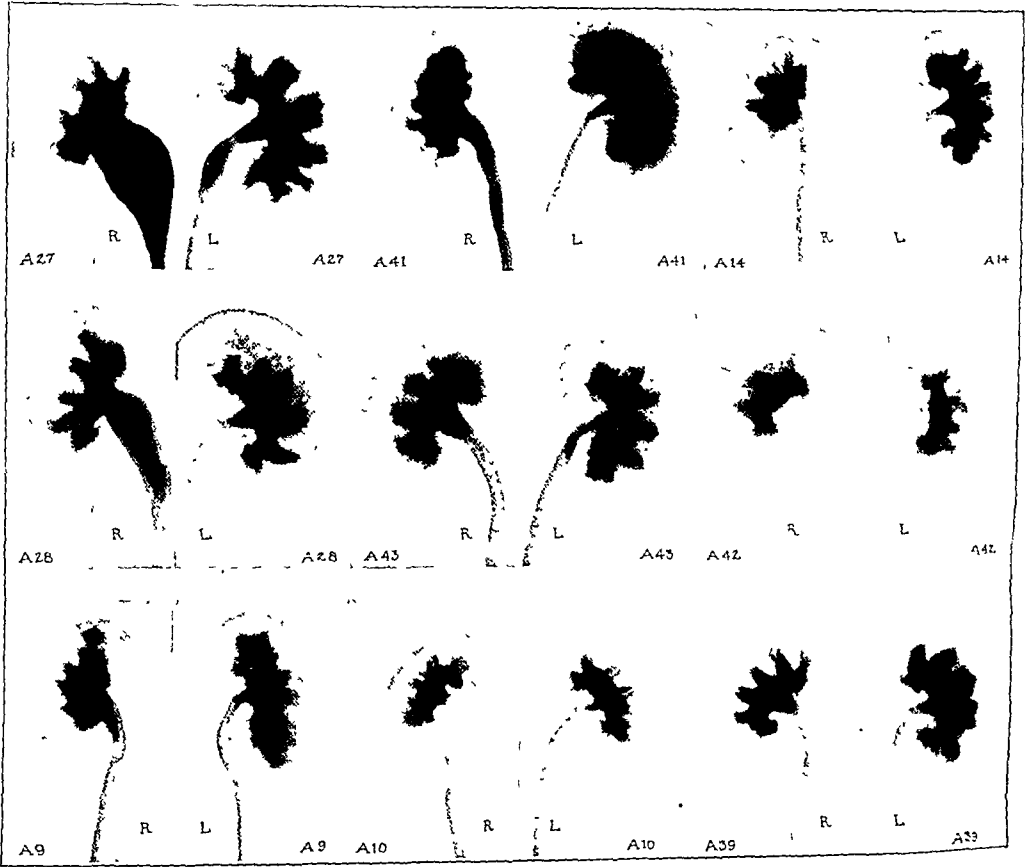

Fig. 9.—Pyelograms of the right and left kidneys of the experiments of group III. These show a tendency of the hydronephrotic pelvis to return to normal although the ureter frequently remained dilated.

The appearance of the kidneys is shown in figure 8.

Pyelograms were made of each kidney (fig. 9). Except for the dilatation of the ureter and extrarenal portion of the pelvis and some extravasation of the sodium iodide in the region of the upper pole, the pyelogram of the right kidney was essentially normal. The pyelogram of the left kidney showed nothing abnormal.

Fig 10.—Sections from the cortex of the right and left kidneys of dog A 27, protocol 13. The right kidney was obstructed for sixteen days and then allowed a repair period of eight hundred seven days, working in "competition" with the undisturbed left kidney. There were no important histologic differences between the right and left kidneys; $\times 65$. *A* indicates the right kidney; *B*, the left.

Histologic Observations.—A few hyalinized glomeruli were present in the left kidney, and many of the glomeruli contained a small amount of serum precipitate within the capsular spaces. Hyaline tubular casts were frequent. In one slide a small abscess was seen in the cortex just beneath the capsule.

In the right kidney, the cortex corticis had entirely disappeared and occasional glomeruli were seen in the most peripheral portions of the cortex. Just beneath the capsule there were a number of thin scars which showed a moderately dense lymphocytic infiltration. These scars ran parallel to the capsule for distances as great as 5 mm., but did not extend more than from 60 to 80 microns into the cortex and probably represented the atrophied cortex corticis. The cortex proper was greatly reduced in thickness, but except for the scarring just described there were no histologic differences in the right and left kidneys of this animal. There was no increase either in the number of atrophic glomeruli or of interstitial fibrous connective tissue.

PROTOCOL 15.—In dog A 34, a female mongrel, weighing 10.8 Kg., hydro-nephrosis was produced for fifteen days followed by a period of repair of four hundred and sixty-five days.

May 18, 1925: The preoperative blood urea was 36.1 mg. per hundred cubic centimeters.

May 25: The right ureter was ligated.

On May 27, the blood urea was 43.2 mg.; on June 9, 43.2 mg.

June 9: The right ureter was implanted into the bladder after a period of fifteen days of complete ureteral obstruction.

On June 11, the blood urea was 35 mg.; June 15, 43 mg.; June 24, 45 mg.; July 8, 48.8 mg. (weight 10.2 Kg. and general condition excellent); July 31, 34.5 mg.; September 24, 25 mg.; October 16, 18.7 mg.; November 13, 17.5 mg.; Feb. 13, 1926, 31 mg.; March 17, 25.3 mg.; April 29, 39 mg.

September 16: The dog was killed, and a complete autopsy was not performed; only the kidneys were preserved. The right kidney was definitely smaller than the left. The greatest amount of parenchyma was found to be situated in the regions of the upper and lower poles, the central portion of the kidney suggesting an atrophic condition. The hilum was enlarged, and the ureter and pelvis were dilated. The left kidney was a normal hypertrophic organ. The weights and measurements of the kidneys were:

	Right	Left
Weight	15.0 Gm.	45.0 Gm.
Length	6.0 cm.	6.3 cm.
Transverse diameter.....	2.8 cm.	4.0 cm.
Anteroposterior diameter.....	1.4 cm.	3.1 cm.
Cortex	2.0 mm.	6.0 mm.

The appearance of the kidneys is shown in figure 8.

Histologic Observations.—Except for the reduction in the thickness of the cortex of the left, there were no histologic differences in the two kidneys. Both were the seat of a mild chronic pyelonephritis, and the radial areas of cortical inflammation contained many atrophic glomeruli and tubules and were densely fibrosed and infiltrated by leukocytes and lymphocytes. Both kidneys showed areas in which the entire width of cortex and medulla appeared normal.

PROTOCOL 16.—In dog A 14, a short haired, male mongrel, weighing 7.8 Kg., hydronephrosis was produced for sixteen days followed by a period of repair of three hundred and sixty-two days.

Dec. 8, 1924, the blood urea was 28 mg. per hundred cubic centimeters.

December 11: The blood urea was 187 mg. The right ureter was ligated.

On December 13, the blood urea was 262 mg.; on December 23, 31.2 mg.

December 23: The right ureter was implanted into the bladder after a period of twelve days of complete ureteral obstruction.

On December 26, the blood urea was 33.5 mg.; Jan. 6, 1925, 27 mg.; January 13, 31.2 mg.; January 27, 26.5 mg. (weight 9.4 Kg. and general condition good); February 13, 267 mg.; February 26, 47 mg.; March 9, 35.1 mg.; March 16, 26 mg.; March 25, 41.6 mg.; April 1, 37.3 mg.; April 10, 25.5 mg.; April 16, 37.4 mg.; May 7, 49 mg.; June 25, 27 mg. (weight 10.8 Kg.); July 22, 23.5 mg.; October 16, 33 mg.; November 13, 40 mg.

December 20: The dog was found dead. Necropsy showed the presence of bilateral pneumonia but the other organs, excepting the kidneys, were normal. The right kidney was definitely smaller than the left, but showed grossly normal parenchyma. The right ureter was not dilated and the anastomosis between the ureter and bladder was patent. The left kidney was a normal hypertrophied organ. The urine which was obtained from the bladder showed no abnormalities. The weights and measurements of the kidneys were:

	Right	Left
Weight	14.1 Gm	44.2 Gm
Length	4.7 cm	6.4 cm
Transverse diameter	2.4 cm	3.7 cm
Anteroposterior diameter	1.6 cm	3.0 cm
Capacity of pelvis	2.0 cc	3.0 cc.
Cortex ..	4.0 mm	8.0 mm

The appearance of the kidneys is shown in figure 8

Pyelograms showed the right kidney and pelvis to be smaller than the left, but otherwise no definite abnormalities were seen (fig. 9).

Histologic Observations.—Except for a slight patchy pyelonephritis and the presence of serum precipitate in the glomeruli, the left kidney showed no pathologic change.

The capsule of the right kidney showed irregular thickening, and the cortex corticis had entirely disappeared. There was a wide zone of interstitial fibrosis in the outer portion of the cortex with short radial extensions at intervals toward the medulla. In this fibrosed zone the glomeruli were concentrated. The glomeruli themselves were small, fibrosed and often hyalinized, and associated with them were many atrophic contracted tubules. Deeper in the cortex proper both glomeruli and tubules appeared normal and here there was no increase in interstitial fibrous connective tissue. The medulla showed patchy areas of fibrosis. This kidney was also the seat of a very mild pyelonephritis.

Protocol 17.—In dog A 28, white male terrier, weighing 14.4 Kg., hydro-nephrosis was produced for twelve days followed by a period of repair of two hundred and seventeen days.

March 6, 1925: The preoperative blood urea was 50 mg. per hundred cubic centimeters. The right ureter was ligated.

On March 9, the blood urea was 60 mg.; March 13, 50 mg.; March 16, 26 mg.

March 18: The right ureter was implanted into the bladder after a period of twelve days of complete ureteral obstruction.

On March 20, the blood urea was 43.2 mg.; March 25, 36.4 mg.; April 1, 42.2 mg.; April 16, 36 mg.; June 25, 43 mg.; July 22, 48.4 mg.; September 24, 43.2 mg.; October 16, 16 mg. (general condition good).

October 21: The dog was killed.

Necropsy.—All the viscera were normal except the kidneys. The right kidney showed a firm parenchyma but was only about one-half as large as the left kidney. The right ureter was somewhat dilated as was also the extrarenal portion of the pelvis. The anastomosis between the right ureter and the bladder was patent. The left kidney was a normal hypertrophied organ. The weights and measurements of the kidneys were:

	Right	Left
Weight	31.5 Gm.	69.2 Gm.
Length	5.3 cm.	6.6 cm.
Transverse diameter.....	3.3 cm.	4.4 cm.
Anteroposterior diameter.....	2.7 cm.	3.9 cm.
Capacity of pelvis.....	6.5 cc.	5.5 cc.
Cortex	4.0 mm.	8.0 mm.

The appearance of the kidneys is shown in figure 8.

Pyelograms were made of each kidney (fig. 9). These showed the right kidney to be smaller than the left with a definite dilatation of its ureter and the extrarenal portion of its pelvis, but the intrarenal portion of its pelvis appeared relatively normal. The pyelogram of the left kidney was normal.

Histologic Observations.—A few fibrosed and hyalinized glomeruli with thickened capsules were seen in the left kidney; otherwise it showed no pathologic change.

There was an irregular thickening of the capsule of the right kidney, beneath which a narrow zone of the cortex showed marked interstitial fibrosis. In this zone there was a concentration of glomeruli and tubules showing many stages of atrophy up to complete obliteration. Some of the glomeruli showed marked reduction in the size of the tufts without reduction in the size of the capsule so that there remained a large empty space between the capsule and tuft. Occasional small capsules were seen in which the tuft had entirely disappeared. There were small radial extensions of this peripheral zone of fibrosis toward the medulla. A wide inner zone of the cortex and the corticomedullary zone appeared entirely normal. There was some radial scarring of the medulla. Figure 11 shows the fibrosed peripheral zone of the cortex and the deeper unchanged zone.

PROTOCOL 18.—In dog A 43, long haired, female mongrel, weighing 14.8 Kg., hydronephrosis was produced for thirteen days followed by a period of repair of one hundred and fifty-four days.

The preoperative blood urea was 27 mg. per hundred cubic centimeters.

June 17, 1925: The right ureter was ligated.

On June 25, the blood urea was 30 mg.; on June 30, 34 mg.

June 30: The right ureter was implanted into the bladder after a period of thirteen days of complete ureteral obstruction.

July 8: The condition of the dog was good. She weighed 14.6 Kg., and the blood urea was 30.3 mg.

On July 31, the blood urea was 24 mg.; September 24, 22 mg.; October 16, 25 mg.; November 13, 31 mg.

December 1: The dog died after an apparent illness of a few weeks.

Necropsy.—There were no external signs of injury. There was a thick purulent exudate throughout the mediastinum. The pleural cavities and lungs were not involved. The esophagus showed no perforations, nor did the trachea or large bronchi. The source of the infection was undetermined. The heart and pericardium were normal. All abdominal organs except the kidneys were normal. The right kidney was slightly smaller than the left. Its ureter and pelvis showed

Fig 11.—Cortex of the right kidney of dog A 28, protocol 17. The kidney had been obstructed for twelve days and allowed a repair period of two hundred seventeen days in "competition" with its undisturbed mate. *A* shows the fibrosed peripheral zone of the cortex, with atrophic tubules and concentration of glomeruli; *B*, the deeper layer of the cortex in which there was no atrophy or interstitial fibrosis; $\times 60$.

a slight degree of dilatation, but the kidney was otherwise grossly normal. The anastomosis between the right ureter and the bladder was patent. The left kidney appeared to be normal. The weights and measurements of the kidneys were:

	Right	Left
Weight	38.1 Gm.	44.2 Gm.
Length	5.9 cm.	6.1 cm.
Transverse diameter.....	4.0 cm.	3.8 cm.
Anteroposterior diameter.....	2.2 cm.	3.0 cm.
Capacity of pelvis.....	5.0 cc.	5.5 cc.
Cortex	6.0 mm.	7.0 mm.

The appearance of the kidneys is shown in figure 8.

Pyelograms of both kidneys were made (fig. 9). Aside from the slight dilatation of the right ureter, no remarkable difference between the two sides was noted.

Histologic Observations.—Except for a reduction of the thickness of the cortex with radial scarring of the medulla of the left kidney, there was no histologic difference between the two kidneys of this animal.

PROTOCOL 19.—In dog A 35, a brown and white female mongrel, weighing 10.2 Kg., hydronephrosis was produced for sixteen days followed by a period of repair of ninety-one days.

May 18, 1925: The blood urea was 29 mg. per hundred cubic centimeters.

May 20: The right ureter was ligated.

On May 25, the blood urea was 41 mg.; on June 3, 43.2 mg.

June 5: The right ureter was implanted into the bladder after a period of sixteen days of complete ureteral obstruction.

On June 8, the blood urea was 48.8 mg.; June 15, 42 mg.; June 24, 42 mg.; July 8, 27.6 mg.; July 31, 26.1 mg. The dog appeared weak and mangy, and weighed 6.8 Kg. on July 8.

September 4: The dog was killed in a fight.

Necropsy.—There was a wound in the chest which opened into the left pleural cavity and also a wound of the left lumbar region through which the left kidney had been lacerated. The dog was somewhat emaciated. The right kidney was small and firm. The anastomosis between the right ureter and the bladder was patent. There was some dilatation of the right ureter and renal pelvis. The left kidney was lacerated, but otherwise seemed to be a normal hypertrophied organ. The weights and measurements of the kidneys were:

	Right	Left
Weight	11.8 Gm.	28.7 Gm.
Length	4.7 cm.	6.7 cm.
Transverse diameter.....	2.7 cm.	3.1 cm.
Anteroposterior diameter.....	1.5 cm.	2.4 cm.
Cortex	2.0 mm.	5.0 mm.

The appearance of the kidneys is shown in figure 8.

The pyelogram of the right kidney showed a rather small organ. The ureter and renal pelvis showed some dilatation but this was not marked.

Histologic Observations.—The left kidney showed no abnormality on histologic examination.

The right kidney showed a complete disappearance of the cortex corticis with a thickened capsule. The capsular thickening was irregular and occasional prolongation of the fibrous connective tissue extended down into the underlying cortex. Only a narrow zone of the cortex adjacent to the medulla contained normal glomeruli and tubules and was comparatively free from the interstitial fibrosis

which invaded most of the cortex and medulla. Here again there was a concentration of atrophic glomeruli in the peripheral zone of the cortex. There was a mild degree of pyelonephritis.

PROTOCOL 20.—In dog A 42, a brindle male mongrel, weighing 13.6 Kg., hydro-nephrosis was produced for thirteen days, followed by a period of repair of seventy-eight days.

The preoperative blood urea was 18 mg. per hundred cubic centimeters.

June 17, 1925: The right ureter was ligated.

On June 25, the blood urea was 53 mg.; on June 30, 42 mg.

June 30: The right ureter was implanted into the bladder after a period of thirteen days of complete ureteral obstruction.

July 8: The blood urea was 67.6 mg., and the weight, 12.5 Kg. The general condition of the dog was good.

July 31: The blood urea was 24.9 mg.

September 16: The dog was killed.

Necropsy.—The organs were essentially normal except the kidneys. The right kidney was smaller than the left but it consisted of normal firm parenchyma. The right ureter and pelvis showed slight dilatation. The anastomosis between the right ureter and the bladder was patent. The left kidney was a normal hypertrophied organ. The weights and measurements of the kidneys were:

	Right	Left
Weight	28.8 Gm.	38.3 Gm.
Length	5.4 cm.	6.0 cm.
Transverse diameter.....	2.9 cm.	3.3 cm.
Anteroposterior diameter.....	2.1 cm.	2.8 cm.
Capacity of pelvis.....	7.0 cc.	2.4 cc.
Cortex	5.0 mm.	7.0 mm.

The appearance of the kidneys is shown in figure 8.

Pyelograms of both kidneys showed a mild degree of dilatation of the right ureter and pelvis, but no other remarkable changes were noted (fig. 9).

Histologic Observations.—There was no histologic difference between the right and the left kidneys except the reduction in width of the cortex of the right kidney.

PROTOCOL 21.—In dog A 9, a mongrel poodle, weighing 8 Kg., hydronephrosis was produced for twelve days followed by a period of repair of seventy-one days.

On Nov. 13, 1924, the blood urea was 37.4 mg.; on November 14, 26.6 mg.

December 5: The right ureter was ligated.

On December 8, the blood urea was 26.1 mg.; December 11, 32.4 mg.; December 13, 46 mg.

December 17: The right ureter was implanted into the bladder after a period of twelve days of complete ureteral obstruction.

On December 23, the blood urea was 46.8 mg.; December 26, 48.5 mg.; Jan. 6, 1925, 37.4 mg.; January 13, 39.2 mg.; January 27, 35.5 mg. (weight, 5.5 Kg.); February 3, 41.6 mg.; February 13, 43 mg. (weight, 5.3 Kg.). The dog developed mange on February 13.

February 26: The blood urea was 67.4 mg. The mange was severe and the general condition was poor. The dog was killed with ether.

Necropsy.—There was some consolidation in the lower lobe of each lung. The liver, spleen, pancreas and adrenals were normal. The small intestine was found to contain a large number of worms. The right kidney was somewhat smaller than the left. The right ureter and pelvis were dilated. The parenchyma of the right kidney was firm and grossly appeared to be normal. The anastomosis

between the right ureter and the bladder was patent. The left kidney was normal. The weights and measurements of the kidneys were:

	Right	Left
Weight	16.0 Gm.	22.0 Gm.
Length	4.6 cm.	5.1 cm.
Transverse diameter.....	2.7 cm.	3.1 cm.
Anteroposterior diameter.....	1.7 cm.	2.3 cm.
Capacity of pelvis.....	3.0 cc.	2.5 cc.
Cortex	4.5 mm.	5.0 mm.

The appearance of the kidney is shown in figure 8.

Pyelograms were made of both kidneys (fig. 9), and aside from the slight dilatation of the right ureter and pelvis no abnormalities were seen in either pyelogram.

Histologic Observations.—There was no histologic difference between the right and left kidneys except the reduction in the cortex of the right kidney.

PROTOCOL 22.—In dog A 10, a short haired, brown female mongrel, weighing 5.5 Kg., hydronephrosis was produced for thirteen days followed by a period of fifty-six days.

The preoperative blood urea was 30 mg. per hundred cubic centimeters.

Dec. 6, 1924: The right ureter was ligated.

On December 8, the blood urea was 56.1 mg.; December 11, 50.1 mg.; December 13, 57 mg.

December 19: The right ureter was implanted into the bladder after a period of thirteen days of complete ureteral obstruction.

On December 23, the blood urea was 59.1 mg.; December 26, 56 mg.; Jan. 13, 1925, 41.6 mg.; January 27 (weight, 5.7 Kg., and general condition good); February 3, 50.6 mg.; February 13, 60.5 mg.

February 13: The dog was killed. She weighed 5.9 Kg.

Necropsy.—The organs were essentially normal except the kidneys. The right kidney was somewhat smaller than the left; the parenchyma was firm; the ureter and pelvis were slightly dilated. The anastomosis between the right ureter and the bladder was patent. The left kidney was normal and somewhat hypertrophic. The weights and measurements of the kidneys were:

	Right	Left
Weight	9.7 Gm.	15.4 Gm.
Length	3.9 cm.	4.8 cm.
Transverse diameter.....	2.2 cm.	2.6 cm.
Anteroposterior diameter.....	1.5 cm.	2.2 cm.
Capacity of pelvis.....	4.0 cc.	3.5 cc.
Cortex	4.0 mm.	4.0 mm.

The appearance of the kidneys is shown in figure 8.

Pyelograms were made of both kidneys (fig. 9), and these were found to be normal except for the dilatation of the right ureter.

Histologic Observations.—The left kidney showed no abnormality on histologic examination other than a mild pyelonephritis.

The right kidney showed a diffuse interstitial fibrosis most marked in the subcapsular zone of the cortex. The capsule was thickened and there was a concentration of glomeruli immediately beneath it. Some of the glomeruli appeared normal and occasional groups of normal appearing tubules extended up into the densely fibrosed cortex corticis. There was a diffuse atrophy of both tubules and glomeruli. Deeper in the cortex there were many radially disposed scars and occasional atrophic glomeruli. The medulla showed a patchy increase of fibrous connective tissue. There was a mild pyelonephritis.

PROTOCOL 23.—In dog A 46, a black and brown male mongrel, weighing 12.6 Kg., hydronephrosis was produced for nineteen days followed by a period of repair of forty-three days.

The preoperative blood urea was 36 mg. per hundred cubic centimeters.

July 1, 1925: The right ureter was ligated.

July 20: The blood urea was 44.2 mg. The right ureter was implanted into the bladder after a period of nineteen days of complete ureteral obstruction.

On July 22, the blood urea was 43.2 mg.; July 27, 53.5 mg.; August 4, 45.6 mg. (weight, 12.6 Kg.); August 13, 36.1 mg.

September 1: The dog was killed.

Necropsy.—Only the kidneys were preserved at autopsy. The right kidney was definitely smaller than the left but the parenchyma was firm and grossly appeared normal. There was a slight dilatation of the right ureter and pelvis of the right kidney. The left kidney was a normal hypertrophied organ. The weights and measurements of the kidneys were:

	Right	Left
Weight	19.5 Gm.	41.0 Gm.
Length	5.5 cm.	6.3 cm.
Transverse diameter.....	2.4 cm.	3.5 cm.
Anteroposterior diameter.....	2.0 cm.	3.4 cm.
Cortex	5.0 mm.	7.0 mm.

The appearance of the kidneys is shown in figure 8.

Histologic Observations.—Left Kidney: No pathologic changes were noted.

In the right kidney, there was a slight diffuse increase in the interstitial fibrous connective tissue throughout the kidney. This fibrosis was most marked in the cortex corticis and the outer zone of the cortex proper. Here there were a number of fine radial scars, broadest at the capsule and extending toward the medulla. In the vicinity of the scars there was considerable atrophy of both tubules and glomeruli, many of the latter being fibrotic. In general, however, the glomerular tufts were plump and cellular. The glomeruli were smaller and approximated one another more closely than in the left kidney.

PROTOCOL 24.—In dog A 39, a brown and white female mongrel, weighing 8.6 Kg., hydronephrosis was produced for sixteen days followed by a period of repair of twenty-four days.

May 18, 1925: The blood urea was 30.5 mg. per hundred cubic centimeters.

May 20: The right ureter was ligated.

On May 25, the blood urea was 30.3 mg.; on June 3, 48.3 mg.

June 5: The right ureter was implanted after a period of sixteen days of complete ureteral obstruction.

On June 8, the blood urea was 41.6 mg.; June 15, 32 mg.; June 24, 34 mg.

June 29: The dog was killed.

Necropsy.—All the organs were normal except the kidneys. The right kidney was definitely smaller than the left and showed some dilatation of the pelvis and ureter. The parenchyma was firm. The anastomosis between the right ureter and the bladder was patent. The left kidney was a normal hypertrophied organ. The weights and measurements of the kidneys were:

	Right	Left
Weight	17.6 Gm.	40.4 Gm.
Length	5.0 cm.	6.2 cm.
Transverse diameter.....	2.7 cm.	4.1 cm.
Anteroposterior diameter.....	1.8 cm.	2.8 cm.
Cortex	3.0 mm.	6.0 mm.
Capacity of pelvis.....	3.5 cc.	4.0 cc.

The appearance of the kidneys is shown in figure 8.

Pyelograms were made of both kidneys (fig. 9). The right kidney appeared definitely smaller than the left and its ureter was slightly dilated, but aside from these changes the two kidneys appeared to be normal.

Histologic Observations.—The glomeruli in the left kidney were large and the tufts plump, in most instances filling their capsules. The organ was very hyperemic, many of the interlobular vessels being greatly distended.

There was marked tubular atrophy of the right kidney with degeneration of tubular epithelium. The atrophy was particularly severe in the cortex corticis and in the outer zone of the cortex proper giving this part of the kidney a compact appearance with concentration of glomeruli. There were many instances of tubular epithelial regeneration, and the regenerated tubules stood out in sharp contrast to the collapsed atrophic ones. Many of the glomeruli in the zone of the cortex had capsules of normal size but only a small portion of the tufts still intact. The greater part of such a glomerular tuft was represented by a granular basophilic mass containing a few fragmented and pyknotic nuclei lying free in the capsular space. Deeper in the cortex there were many normal appearing glomeruli, but here as well as in the medulla there were many collapsed tubules with degenerated epithelium.

In these experiments, which bear more directly on the subject of renal atrophy of disuse, the right kidney was injured by the production of a complete ureteral obstruction which existed in the various experiments from twelve to nineteen days. After the obstruction was relieved, the injured right kidney was placed "in competition" with the hypertrophic left kidney, and this period extended from twenty-four to eight hundred and seven days. According to Hinman's theory, the right kidney was thus placed at a distinct disadvantage, first because of the injury itself and secondly because its mate had become hypertrophied and accustomed to having the entire demand for renal function placed on it.

The important questions which arise concerning the fate of the right kidney are as follows: Does it undergo progressive atrophy and become a functionless and worthless organ? What are the gross and histologic changes that take place in it?

In the early part of the "competitive period" we must expect some rapid changes to occur in the right kidney. With relief of the obstruction the kidney soon changes from a large dilated structure to a considerably smaller and firmer organ. The ureter and extrarenal portion of the pelvis frequently remain permanently dilated, but the dilatation of the intrarenal portion of the pelvis may entirely disappear as in dog A 28, protocol 17 (figs. 8 and 9). In no experiment did the atrophy approach completeness and, in fact, there is no conclusive evidence that any atrophy occurred following the release of the hydronephrotic pressure. From our histologic studies it would appear that during the period of ureteral obstruction numerous uriniferous units (tubules and glomeruli) were either destroyed or so severely damaged that necrosis

followed in spite of the removal of the obstruction. These damaged units gradually disappeared, and with their disappearance there developed considerable interstitial fibrosis, and within a period of ten or eleven weeks even the fibrous tissue had disappeared. It seems possible that this gradual but complete disappearance of these injured uriniferous units may account for the smaller relative size of the right kidney in some of those experiments in which there was a long period of repair rather than a true progressive atrophy of disuse.

The right kidney from dog A 27, protocol 13, seemed to be a functioning organ and by weight made up 36 per cent of the total renal mass even though the period of "competition" had lasted eight hundred and seven days. Both grossly and microscopically (figs. 8 and 10), this kidney consisted of tissue which was important, if not for active function, certainly as renal reserve. The excretion of phenolsulphonphthalein by this kidney was 14 per cent in 14 cc. of urine in one hour with an appearance time of eight minutes. The left kidney excreted 44 per cent of the dye in 20 cc. of urine with an appearance time of four minutes. The right kidney in dog A 41, protocol 14, constituted only 25 per cent of the total renal mass, but it had not undergone complete atrophy even though its ureter had been completely obstructed for sixteen days and the kidney had remained in "competition" with its hypertrophied mate for seven hundred and twenty-eight days. This injured kidney excreted only 10 per cent of phenolsulphonphthalein in 8 cc. of urine in one hour with an appearance time of fifteen minutes. The left kidney excreted 50 per cent of the dye in 18 cc. of urine in one hour with an appearance time of four minutes. The right kidney of dog A 34, protocol 15, also constituted only 25 per cent of the total renal mass and still showed some hydronephrosis after a repair period of four hundred and sixty-five days. The parenchyma of this organ was limited almost entirely to each pole, and grossly this kidney appeared to be more atrophic than any of the others.

If the injured kidney underwent progressive atrophy, we should expect the experiments of the longest "competitive" period to show the greatest degree of atrophy. This is not at all striking in these experiments. The percentages of the renal mass made up by the right kidneys in the experiments of longer duration are somewhat below those in the experiments of short duration, but this difference may well lie within the limits of experimental variation or may be explained by the histologic observations. Some of the experiments showed a rather surprising degree of repair rather than progressive atrophy. This was especially marked in dog A 43, protocol 18, in which after a period of thirteen days of complete ureteral obstruction and a period of repair of one hundred and fifty-four days the relative weights of the kidneys were almost the same.

The studies of the blood urea in these experiments showed no constant or definite changes. In some of the animals a temporary rise was noted after the ligation of the right ureter.

The histologic studies in this group of experiments are especially noteworthy. The left, undisturbed kidneys of these animals served as controls and in most instances were normal. One animal showed changes indicative of chronic, diffuse glomerular nephritis, while several were the seat of a pyelonephritis which was in no case severe. The glomerular tufts were in general plump and hyperemic and often there was a collection of serum precipitate within the capsules.

The right kidneys were hydronephrotic and showed changes that varied with the length of the recovery period. This variation was not absolutely uniform, some animals showing greater repair in shorter periods of time than others. In general, however, the following sequence of changes could be traced throughout the series.

The right kidney of dog A 39, protocol 24, which was obstructed for sixteen days and followed by a repair period of twenty-four days, showed changes only slightly more advanced than those observed in the right kidneys of the dogs of series I. The damage was most severe in the cortex corticis and in the outer zone of the cortex proper while the deeper zone of the cortex appeared normal (fig. 11). There was widespread degeneration of tubular epithelium with tubular atrophy and collapse. The glomeruli appeared to be concentrated in the damaged zone, and although the capsules were of normal size the tufts were exceedingly small. The decrease in the size of the glomerular tufts was not due here to a contraction but to loss of substance, and frequently a mass of necrotic cellular tissue still clung to the remnant of tuft while in other instances the capsular space was partially filled with a structureless granular basophilic mass containing a few fragmented or pyknotic nuclei. Some of the tubules were represented by a small group of degenerated epithelial cells enclosed by a basement membrane while others were lined by young regenerated epithelium containing mitotic figures. With a longer period of repair the fibrous connective tissue reaction to the injury was manifest. The cortex corticis was completely atrophic and persisted only as an irregular thickening of the capsule. There was marked interstitial fibrosis of the outer zone of the cortex proper with radial extensions of the scarring toward the medulla. There was contraction of the fibrosed zones with concentration of glomeruli many of which showed degeneration and fibrosis. Later many of the glomeruli shrank until only a small scar marked their location. The damaged tubules went on either to complete atrophy and disappearance or to epithelial regeneration and restitution. In this stage there was considerable fibrosis of the medulla and in some cases there was a proliferation of the perivascular fibrous connective tissue.

In five of the nine animals in which the period of repair was seventy days or more there was no histologic difference between the right and left kidneys except the reduction in thickness of the right cortex (fig. 10). There was no trace of the destroyed renal tissue in the right kidney of these animals. This observation was of especial interest in view of the fact that there was a definite mass reduction in the majority of the right kidneys and yet there were no signs of the atrophied structures. This would suggest that a glomerulus damaged in the course of hydronephrosis becomes atrophic and can eventually disappear without leaving any trace.

As has already been mentioned, the cortex corticis and outer zone of the cortex proper suffered the greatest damage while the deeper zone of the cortex and the corticomedullary zone appeared unchanged in recent as well as older injuries. This would seem to indicate that the distribution of the damage was associated with the vascular supply of the organ and that the arterial compression incident to the hydronephrosis affected to the greatest degree those glomeruli which were supplied by the terminal branches of the interlobular arteries and that those glomeruli whose blood supply was derived from the larger vessels closer to the arcuate arteries were not damaged by such periods of hydronephrosis as these kidneys experienced (fig. 11). Hinman and Morison² arrived at the same conclusion by arterial injection experiments, and stated that that portion of the kidney receiving the largest and most direct blood supply persisted longest and continued to secrete against the intrapelvic pressure.

SUMMARY AND CONCLUSIONS

Our experiments may be divided into three groups:

Group I: In these experiments the right ureter was completely obstructed for periods varying from thirteen to sixteen days, following which the animals were killed in order that the changes thus produced in the kidneys might be studied. These experiments demonstrated that such a period of ureteral obstruction caused a fairly marked degree of hydronephrosis and renal damage.

Group II: In these experiments the right ureter was completely obstructed for periods varying from eleven to nineteen days, following which the obstruction was relieved and several days later the hypertrophic left kidney was removed. In this way the entire load of renal function was placed on the injured kidney. The period of repair varied between thirty-four and eight hundred and twenty-eight days.

2. Hinman, F., and Morison, D. M.: Experimental Hydronephrosis: Arterial Changes in Progressive Hydronephrosis of Rabbits with Complete Ureteral Obstruction, *Surg. Gynec. Obst.* **42**:209 (Feb.) 1926.

These experiments definitely showed that the injured kidney could undergo a remarkable degree of repair and hypertrophy if the demand were placed on it.

Group III: In these experiments the right ureter was completely obstructed for periods varying from twelve to nineteen days, following which the obstruction was relieved and the injured kidney was allowed to act in "competition" with its undisturbed and hypertrophic mate. This period of "competition" varied between twenty-four and eight hundred and seven days.

This group of experiments bears more directly on the question of renal atrophy of disuse. In no experiment did the injured kidney go on to complete atrophy even though in four of the experiments the period

TABLE 3—*Data on Dogs with Repair of Hydronephrotic Kidney with the Hypertrophic Mate Undisturbed*

Protocol	Duration of Complete Obstruction of Right Ureter, Days	Period of Repair of Right Kidney, Days	Weight of Kidneys, Gm		Percent age of Total Renal Mass	
			Right	Left	Right	Left

of "competition" lasted from one to over two years. Instead of complete atrophy we found that the injured kidneys represented from one-fourth to almost one-half the total renal mass. The pyelographic studies showed that in most instances there was a return to a relatively normally shaped pelvis, although frequently the extrarenal portion of the pelvis and the ureter remained somewhat dilated.

The histologic studies, which were made in all of the experiments, may be summarized as follows:

1. The immediate effects of renal obstruction were manifested first by tubular degeneration and later by glomerular damage. Many of the glomerular tufts underwent partial or complete necrosis with subsequent disappearance of all or part of the renal unit.

2. Those kidneys which after a period of total ureteral obstruction ranging from twelve to nineteen days were allowed by relief of the obstruction to work in "competition" with their hypertrophic and undisturbed mates showed no evidence of progressive atrophy. The injured

renal elements either recovered or completely disappeared. In those experiments in which the period of repair was seventy days or more, histologic differences between injured and noninjured kidneys were not seen in five of nine animals. The other four showed varying stages of recovery.

3. Those kidneys which after a period of total ureteral obstruction ranging from eleven to nineteen days were forced to carry the entire functional load recovered rapidly, and no trace of the damaged renal units could be seen after a period of repair of forty-two days or more.

Our experiments did not demonstrate any renal atrophy of disuse and, in fact, strongly suggest that such atrophy does not occur.

In view of the experimental data presented, the theory of renal counterbalance need not be seriously considered in deciding the surgical treatment for certain renal lesions.

THE DELBET APPARATUS AND THE END-RESULTS*

EDWARD T. CROSSAN, M.D.

PHILADELPHIA

The ability to apply knowledge is a valuable possession. By this faculty, Delbet has applied the common knowledge of surface anatomy to the development of a new treatment for fractures of the leg and of the ankle. He has utilized the prominence of the malleoli and the projections of the internal tuberosity of the tibia and of the head of the fibula as points d'appui for a splint which will fix the fracture without immobilizing the knee or ankle. With good function as the goal of the treatment, Professor Delbet could not have overlooked a method of securing good reduction and solid union.

Good reduction easily secured, consolidation of the fracture stimulated, good function restored in a comparatively painless manner and the disability reduced to a minimum period without the aid of physiotherapy are the benefits I hope to demonstrate by describing again the Delbet apparatus and by reporting the end-results with this method of treatment.

DELBET APPARATUS

Materials.—1. A thin, flat board is used, which is covered on one side by zinc and to one end of which is attached a pulley at such a height that traction over it will be directly in the long axis of the bones of the leg (fig. 1, A). The pulley is movable laterally so that any lateral deformity can be corrected without disturbing the fracture.

2. A scultetus, or many-tailed bandage, made long enough to extend from the heel to the knee is used; the loose ends on each side are wrapped in a narrow piece of cardboard for convenience in handling.

3. Four splint forms made of crinoline are needed. Figure 2 shows in detail the measurements and the shapes of the forms. The forms are basted down the middle (the dotted line on the form in figure 2). Plaster of paris is incorporated in each layer of the crinoline as in the preparation of a plaster bandage,¹ and the forms, with their meshes filled with the dry powder, are wrapped in waxed paper and stored until occasion for use arises.

METHOD

Preliminary Procedures.—The board, zinc side up, is placed beneath the fractured limb. To prevent rotation of the fragments, the toes of the injured limb are held by an assistant. The leg is washed with soap and water, rinsed with

* Submitted for publication, March 16, 1929.

* From the clinic of Dr. A. P. C. Ashhurst, Episcopal Hospital.

1. This method of the preparation of the forms differs from the directions laid down by Delbet, and the cause for the modification will be noted later in the paper.

Fig. 1.—Method of applying traction: *A*, board; *B*, scultetus; *C*, traction loop, and *D*, overlapping of the flannel piece for the traction loop.

Fig. 2.—Measurements and shapes of splint forms.

alcohol and powdered; shaving is not necessary. Next, the scultetus is gently worked into position between the leg and the board (fig. 1, *B*).

Reduction.—A stirrup is made by using two strips of narrow flannel bandage (3 by 45 cm.). One strip is placed beneath the tendo achillis and above the heel. The second strip is passed over the dorsum of the foot, just distal to the ankle joint. The strips are crossed on each side below and posterior to the malleolus, and at the point of overlapping they are stitched together (fig. 1, *D*). The four loose ends (two from each strip) are carried to a suitable distance below the sole of the foot, and a loop is made by tying or stitching the ends together. To the loop (fig. 1, *C*) is attached the rope which will carry the weights.

The weights are added gradually so as to prevent spasm of the muscles. No manipulations (attempts to push fragments into place) are employed. If the preceding instructions are observed there is little pain, and no anesthetic is required. The pain ceases as soon as the weight begins to act. Repeated measurements are made to determine reduction. When reduction has been obtained, the splint is applied without disturbing the traction apparatus.

Application of the Splint.—Step 1: The ankle and the knee forms (fig. 2) are immersed in water, and when they have been saturated, they are spread out on a table and plaster of paris powder is sprinkled over both sides of each splint.

Step 2: The ankle form is placed in position by (*a*) passing one of the narrow ends through the gap which exists between the heel and the point where the calf of the leg comes into contact with the board; (*b*) gentle traction pulls through one of the wings (the area 12 cm. wide in figure 2); (*c*) the notch in the form is placed above the os calcis; (*d*) the wings are placed opposite the malleoli and the lower end carried down to within 1 cm. of the sole, and (*e*) the narrow ends and the entire form of crinoline are spread out on the board.

Step 3: The knee form (fig. 2) is passed under the knee, across the popliteal space. By seesaw motions it is moved downward to a position below the tibial tubercle, and the ends are spread out on the board.

Step 4: During steps 2 and 3, an assistant soaks the side forms by the method described in step 1. These forms are applied to the sides of the leg from the knee to within 1 cm. of the sole and then turned upward on themselves so as to provide an extra support for the subastragalar joint and the ankle joint.

Step 5: The spread out ends of the ankle piece are carried obliquely upward across the front of the leg and onto the opposite side splint. The ends must be crossed at or slightly above the point where the tendon of the tibialis anticus becomes subcutaneous. This ankle piece thus holds the lower ends of the side splints against the malleoli and the sides of the leg.

Step 6: The ends of the knee piece are carried across the front of the leg over the tibial tubercle, and serve to hold the upper ends of the side splints against the leg. Figure 3, *A* shows the splint applied and the manner of crossing of the extremities of the ankle and knee forms.

Step 7: The ends of the scultetus (fig. 1, *B*) are unwrapped from their cardboard and the strips are crossed obliquely from below upward.

Step 8: When the plaster has set firmly enough to give a clear sound on tapping with the fingers, the weights are removed and the stirrup is cut on the dorsum of the foot, and is removed entirely. The continued traction prevents displacement of the fragments during the application and setting of the splint. Traction should not be continued longer than twenty-five minutes, because of the danger of sloughs over the dorsum of the foot or on the heel.

Fig. 3.—*A*, anterior aspect of splint applied. *B*, posterior aspect of same splint. *C*, lateral aspect of same splint. *D*, the flexion of the knee is not impeded by the splint.

With the aid of two assistants, the surgeon usually can apply the Delbet apparatus in from ten to twelve minutes, including the time allowed for the weight traction to overcome the deformity. Figure 3 shows the splint applied.

PRECAUTIONS

The precautions to be observed in applying the splint are as follows:

1. No attempts at manual reduction should be made during the process.
2. The knee pieces should not be carried too high because full flexion of the knee would be prevented.
3. The ankle pieces should be crossed above the point where the *tibialis anticus* becomes subcutaneous. If they are crossed below this point, a pressure sore will result from rubbing of the tendon against the edge of the splint when the foot is dorsiflexed.
4. The side pieces should not extend as far down as the sole.
5. Traction should not be too prolonged.

TREATMENT AFTER APPLICATION

The patient is returned to bed, the leg is elevated high (six pillows) and is surrounded by ice bags. By the strict observance of these regulations swelling can be prevented. If swelling should occur, a vicious cycle would be established resulting in troublesome ulcers.

The day following the application, the scultetus is removed, and on the same day active motions of the knee and ankle are started. Most patients are able to raise the limb from the pillows and kick it around actively the morning after the splint has been applied. In a week or ten days, the patient is removed from bed and is advised to bear weight on the injured limb with the support of crutches; at each step the patient bends the knee, bends the ankle and comes up on the toes. During the third or fourth week the crutches are discarded for a cane, and at about this time some patients, particularly children, walk without any support. The splint is removed in six weeks, and the patient returns to work as soon as confidence in the injured limb is regained. Many patients will not use the injured limb as advised, unless the surgeon takes the trouble to walk with them at first to instruct them. When they have learned, they will walk, gladly.

SUMMARY

The fracture, as all fractures should be, is reduced immediately. The reduction is by gradual traction, and the fracture is immobilized by a splint which does not interfere with motions of the knee or ankle (fig. 3). Walking encourages consolidation, because the medullary

callus is approximated in the weight-bearing.² Displacement of the fragments is prevented by the close application of the side splints to the bony prominence of the leg.

END-RESULTS

In the compilation of the accompanying tables, I have adhered strictly to the definitions of the Fracture Committee of the American Surgical Association:

1. The anatomic result means the position of the fragments at the time of union.

2. A bad anatomic result is one in which there is gross deformity, or shortening of more than 2 cm.

3. Moderate anatomy is a variant of the foregoing results.

4. Good anatomy indicates that there is no appreciable deformity.

5. If there are no symptoms, the result is classed as good function.

6. Pain in damp weather or swelling, limp or lessened endurance classify the result as moderate function.

7. Bad function means that the earning capacity was reduced, that a change of occupation was necessary or that there was a serious interference with the functions of the joints.

The splint was first used in the Episcopal Hospital during October, 1922. In this study are included all of the patients with fractures of the leg and of the ankle admitted to Dr. Ashhurst's service between October, 1922, and October, 1927, excluding those of 1928, because in some of the cases, the results are too recent to be classed as end-results.

During the five year period ninety-nine patients were admitted. In two of the patients the fractured leg was the less severe injury, and death occurred a few hours after admission. A third patient had an amputation of the leg for uncontrollable hemorrhage from a compound fracture. A fourth patient, not treated by the Delbet method, died from fat embolism soon after the removal of a Steinmann pin.

Seventeen of the ninety-five cases of fractures were unsuitable for the Delbet method, and twelve other patients were not treated by it; the site of the fracture and the variety of the fracture in these twenty-nine cases are shown in tables 1 and 2. At this point it should be noted that the unsuitable cases are (1) fractures above the middle third of the leg because the immobilization for such fractures should include the knee, and (2) severe compound fractures or fractures complicated by severe lacerations or abrasions, because the splint interferes with dressings; however, in these cases the splint can be used when the wounds are healed.

2. J. F. Cowan recently showed that the separation of the medullary callus is probably the cause for nonunion (*Ann. Surg.* 88:749, 1928).

Sixty-six patients, or 87 per cent of the suitable cases, were treated by the Delbet method, and if the twelve patients noted in table 2 had had this treatment, the results to be reported subsequently would have been more impressive. Fifty-three of the sixty-six patients treated by the Delbet method have been traced: one patient died of carcinoma of the stomach soon after discharge from the hospital and is excluded from the study.

In table 3, the site and the variety of the fractures of the patients not traced are shown. Table 4 shows the variety of fractures, the site and the age incidence of the traced cases. By comparing tables 3 and 4, it will be seen that the fractures of patients not traced were not more severe than those of patients who were followed; also, the age incidence in the two groups is nearly the same. One of the untraced patients, a fat woman, who could not be induced to walk, had delayed union on discharge (refused operation), and she probably has a bad result.

In 1921, Dr. Ashhurst and I reported before the American Surgical Association³ the end-results of a series of 100 cases of fracture of the leg and ankle in which the patients were treated in Dr. Ashhurst's clinic at the Episcopal Hospital, and in table 5 I have abstracted those results to serve as a standard for comparison with the present report. There are few compound fractures in the present series; therefore, table 5 does not include the results of any compound fractures.

In table 6 are recorded the results of the fifty-two traced cases. The results do not represent the work of one surgeon, nor of a specialized group; a large number of the splints have been applied by many different resident physicians and interns.

There has not been any change in the good anatomic results of the series in table 6 over the series in table 5, and this observation was to be expected because good reduction in most cases can be obtained by one means or another—skeletal traction, open reduction, etc. In this

³ Ashhurst, A. P. C., and Crossan, E. T.: Prognosis and Treatment of Fractures of Leg and Ankle: End-Results in 100 Patients, Arch Surg. 7:601 (Nov.) 1923

series, however, reduction was secured in all of the cases by the closed method and without any skeletal traction, whereas, in nineteen of eighty-five cases of simple fractures, in the report of 1921, reduction was obtained by the following methods: six platings, six screw fixations at the ankle, four cases of skeletal traction (Steinmann) and two tenotomies of the tendo achillis. The present report seems to prove that reduction of a fractured leg is more easily secured by the Delbet method of traction.

Good functional results in this series (table 6) were obtained in forty-four cases, or 85 per cent, an increase of 10 per cent over those shown in table 5. In the report of 1921, 85 per cent of the patients who had good anatomy had good function as compared to 93 per cent with good function in patients with good anatomy treated with the

Delbet splint (table 6). It is possible that a higher percentage of good functional results in an accurately reduced fracture will be obtained by the latter method, because there are no fibrous contractures of the muscles nor of the ligaments; however, I believe that the improvements in the second report can be attributed to the absence of any operative procedure in this group. Experiences and observations have convinced me that there is a higher percentage of good functional results in fractures reduced by the closed method than in those reduced by operative procedures. In the series of operative reductions reported in 1921 (included in the results of table 5), only 73 per cent of the good reductions resulted in good function, which is 12 per cent less than the results in the group here reported (table 6). Good reduction easily secured will give the best functional results.

The termination of disability denotes the restoration of good function in most cases of fractures; therefore, the period of disability

should be a fairly accurate index of the efficacy of the method of treatment. In addition to good anatomy, good function depends on the restoration of motion in the joints bordering the fracture, on the reeducation of the muscle groups and on the establishment of an efficient venous return. Immobilization of a fracture of the leg or of the ankle by a circular cast or by a molded plaster (Stimson) splint is always followed by stiffness of the ankle, the knee or both joints, and by swelling of the leg. With the Delbet splint there is no artificial support to the venous column, there is no interference with the motions of the points (except the astragalocalcanean), and there is no hindrance to muscle action and muscle pumping on the veins; therefore, the stiff-

Fig. 4.—Swelling of left lower extremity after the removal of a circular cast.

ness mentioned, or the swelling as shown in figure 4, is rarely seen. Furthermore, with the Delbet splint, confidence in the injured limb returns at an early date because of the weight-bearing during consolidation. With good reduction, immobilization of a fractured leg or ankle by the Delbet splint should reduce the disability to a minimum period.

In a series of thirty-seven adults, the disability was shown in thirty-five.⁴ The average disability of this group was three and one-half months, a reduction of one-half month, or 25 per cent, over the period

4. One of the two patients in whose cases the period of disability is unknown had an incomplete fracture of the tibia; on account of litigation, he refused to tell the period of disability. The other patient, with a fracture of the shafts of the tibia and fibula, returned to Italy.

noted in the footnote of table 5, and a reduction of nine tenths of a month over a series reported by the American Surgical Association in 1921. In only one of thirty-five cases were baking and massage used, which means that there has been a great saving of time and money. There has been an increase of 2 per cent in the bad anatomic and of 1 per cent in the bad functional results; however, the percentages in both groups are less than those reported by the American Surgical Association. The 4 per cent with bad anatomy and the 3 per cent with bad function represent three patients; one (C. G.) had bad anatomy and bad function, a second (H. B.) had bad anatomy and moderate function, and the third (R. R.) had good anatomy and bad function. Two of the bad results are directly traceable to failure of the splints to harden.

During the first eighteen months that the splint was used, soft splints were a frequent occurrence. During that period the forms were pre-

TABLE 8—Results Since January, 1924 (Twenty-Nine Patients Over 15 Years, Twelve Under 15 Years) *

* The period of disability of twenty nine adults was two and eighty six hundredths months (two and seventy six hundredths months for fractures of the leg and two and ninety four hundredths for fractures of the ankle)

pared by immersion in a creamy mixture made by adding plaster of paris to water, the method prescribed by Professor Delbet.

Early in 1924, at the suggestion of Dr. Winter, then a resident physician, Dr. Ashhurst adopted the modification noted previously in the discussion of splint forms under the heading materials. Since January, 1924, there has been only one soft splint,⁵ and in this instance the plaster cream method was used.

In table 8, I have compiled the results since January, 1924. In this group there have not been any bad anatomic results and only one bad functional result. The good anatomic and the good functional results have not materially changed. The average period of disability in this group of twenty-nine adults, however, was two and nine-tenths months, a reduction of one and one-tenth months over the series of 1921. The period of disability in this group, I believe, is about the minimum that can be obtained by any method.

5 A soft splint replaced by Stimson was followed by peroneal palsy (R R, case 2 under bad function)

In this series of fifty-two patients, there were twelve who did not obtain both good anatomy and good function. The deformities and the disabilities of the twelve patients are as follows:

Moderate Anatomy (Seven Cases).—CASE 1.—A child, aged 9 years, with a fracture of the shaft of the tibia, regained perfect function but had a slight bowing at the site of fracture.

CASE 2.—R. W., a man, aged 43, had had a fracture of the lower ends of the tibia and fibula (A3⁶) for which he had been treated in another institution for three weeks. Final examination showed bowing at the site of the tibial fracture and a shortening of 0.5 cm.; joint motions were normal, and he was free from symptoms. He returned to the same work in three months, and his wages were the same. The result was classed as good function.

CASE 3.—W. J., a man, aged 54, as a result of fractures of the lower third of the tibia and fibula, had a moderate fulness over the tibial fragment due to overriding. Shortening could not be measured, because the other leg was markedly deformed as a result of a fracture sustained eighteen years before. He returned to the same work, earned the same wages and was free from symptoms. The result was classed as good function.

CASE 4.—N. D., a woman, aged 54, had a fracture of the lower end of the tibia and of the external malleolus. Relatives reported that she had pain for two years and was disabled for one year. The final x-ray picture at the hospital showed slight posterior displacement of the lower fibular fragment. The result was classed as moderate function.

CASE 5.—S. P., a man, aged 42, had a fracture of the lower ends of the tibia and fibula (A3). At the final examination a convexity was noted over the tibial fracture without shortening. In three months he returned to the same work and earned the same wages. There was perfect function of all the joints, but because he limped slightly, the result was classed as moderate function.

CASE 6.—A. D., aged 52, had a fracture of the lower ends of the tibia and fibula (A3). On account of slight valgus the function was classed as moderate anatomy. The patient returned to work in ten weeks, but the leg swelled at the end of the day, on account of which the result was considered moderate function.

CASE 7.—J. N., aged 50, had a fracture of the middle third shafts of the tibia and fibula. The function was considered a moderate anatomic result because of convexity over the tibial fracture and a shortening of 0.5 cm. The patient returned to the same work in fifteen weeks, earned the same wages and had no symptoms, and therefore was considered as having good function.

Moderate Function (Six Cases).—CASE 1.—N. D., case 4 under moderate anatomy.

CASE 2.—S. P., case 5 under moderate anatomy.

CASE 3.—A. D., case 6 under moderate anatomy.

CASE 4.—E. C., had a Pott's or B2 fracture with good anatomy, but dorsiflexion of the ankle was limited to 90 degrees.

6. In the case reports, A3 indicates a fracture of the lower end of the fibula plus a fracture of the whole lower end of the tibia. B2 represents a fracture of the internal malleolus plus a fracture of the fibula. A1 indicates a fracture of the lower end of the fibula only. (Ashhurst, A. P. C., and Bromer, R. S.: Classification and Mechanism of Fractures of the Leg Bones Involving the Ankle, Arch. Surg. 4:120 [Jan.] 1922.)

CASE 5.—L. B. had a bimalleolar fracture with excellent anatomy, but had a rigid flatfoot. The patient returned to the same work in fifteen weeks.

CASE 6.—H. B., to be noted under bad anatomy.

Bad Anatomy (Two Cases).—CASE 1.—G. C., aged 32, had fractures of the lower end of the tibia and external malleolus (B2). Two Delbet splints failed to harden. Final examination three years after injury showed marked valgus. The patient had constant pain, was disabled nine months, and the earning capacity was "considerably reduced." The result also was classed under bad function.

CASE 2.—H. B., aged 54, had a fracture of the shafts of the tibia and fibula. Three Delbet splints failed to harden. The final result was a marked prominence over the tibial fracture, a shortening of the leg of 1 cm. and a limitation of flexion of the knee at 90 degrees. The patient returned to the same work in nine months and earned the same wages. The result was classed previously under moderate function.

Bad Function (Two Cases).—CASE 1.—G. C., case 1 under bad anatomy.

CASE 2.—R. R., a woman, aged 35, had an oblique fracture of the lower end of the fibula (A1). Two Delbet splints failed to harden. Stimson splints were applied and on removal a peroneal palsy was noted, which has persisted for three years.

CONCLUSIONS

Though the study of the entire five year period shows an improvement in functional results and a reduction of the period of disability, I believe that the results since January, 1924, are more representative of what can be accomplished by the Delbet apparatus. With this method, the return of function and the period of disability are dependent on the patient's persistence in the use of the injured member. Walking on the injured leg with the splint does not cause pain; it is timidity which must be overcome. Reduction of the fracture is easily secured, and there is nothing complicated about the application of the immobilizing apparatus. There are, of course, certain precautions to observe.

TRAUMA TO CENTRAL NERVOUS SYSTEM

ITS EFFECTS ON CARDIAC OUTPUT AND BLOOD PRESSURE AN EXPERIMENTAL STUDY *

ALFRED BLALOCK, M.D.

AND

HUBERT B. BRADBURN, M.D.

NASHVILLE, TENN.

Operations on the central nervous system are frequently accompanied by a marked diminution in the blood pressure. This decline in pressure, however, is not of as grave concern as a like drop in blood pressure during an abdominal operation. The pressure may reach a low level during an operation on the central nervous system, but if the operative procedure is stopped immediately, the pressure will usually rise without any artificial aid. In a report from the surgical clinic of Dr. Harvey Cushing, Bird¹ stated, "During operations for intracranial tumors, patients have been observed who, though their blood pressure remained too low to be recorded for from thirty minutes to three hours, recovered after spontaneously 'picking up' or following transfusion, without detectable injury to nervous tissue or other permanent ill effect." Most of these patients had lost a moderate amount of blood.

The use of the word "shock" is intentionally avoided in the title of this paper because the opinion has been expressed by several competent investigators that the syndrome usually entitled "shock" cannot be produced by injury to the central nervous system. Vincent,² from his experience during the war, stated that he never saw a case of shock which resulted from an injury which was limited to the central or peripheral nervous system. Mann³ said that it was impossible to produce shock in a dog without opening the abdomen, without inducing hemorrhage or without traumatization of the medullary centers. He stated further that an animal with a very low blood pressure owing to section of the spinal cord in the lower cervical or upper thoracic region is not in a condition of surgical shock, because upon withdrawal of the anesthetic the animal will regain consciousness and respond to stimuli applied around the head. In Mann's experiments, the fall of blood

pressure following section of the cord was no greater than the decrease which immediately followed section of the abdomen and exposure of the viscera. He was unable to produce shock in anesthetized animals after hours of traumatization of the great nerve trunks. Guthrie⁴ and Wiggers⁵ were able to produce what they considered as shock, the former by prolonged stimulation of the brachial plexus, the latter by stimulation of sensory nerves or by crushing the testes. Shock was not produced in all animals in which these methods were used. Guthrie stated, "Susceptibility varied greatly in different dogs. Some animals readily succumbed to brachial nerve stimulation alone; others only when nerve stimulation was combined with opening the abdominal cavity and visceral manipulation; while others were highly resistant under both methods."

The purpose in this paper is to record the changes observed in body temperature, pulse rate, maximum and minimum arterial blood pressures, cardiac output and consumption of oxygen produced by trauma to the cerebrum, the cervical cord and the thoracic cord.

METHOD

Dogs were used in all of the experiments. The anesthetics which were employed in different instances were morphine, chloralose and barbital. The anesthesia produced by morphine was not sufficiently profound during the stage of the operation and it was supplemented by light ether anesthesia. In most instances, the following procedure was carried out: After the animals had been narcotized for varying intervals of time, control determinations of the various factors were made. An operation was then performed which had for its object the exposure of the dura overlying the area of the central nervous system which was to be traumatized. The studies were repeated at this stage. The dura was then opened without trauma to the brain or cord, and the third series of studies were performed. The brain or cord area was then traumatized with the finger, and varying numbers of studies on the various functions were performed. The arterial blood pressure readings were obtained by placing in the femoral artery a cannula which was connected with a mercury manometer; maximum and minimum valves were used in most instances. A Benedict spirometer was employed in determining the consumption of oxygen. The connection between the animal and the spirometer was made either by the use of a tracheal cannula or by a specially constructed rubber mask which made an airtight closure over the animal's mouth. Samples of blood were withdrawn under oil and placed under oil in order to avoid contact with air. Arterial blood was obtained from the femoral artery and mixed venous blood from the right side of the heart. The analyses of the blood gases were performed with the van Slyke-Neill manometric apparatus. The output of the heart was computed by the Fick principle:

$$\frac{\text{Oxygen consumption per minute}}{\text{Arterial oxygen content minus venous oxygen content}} = \frac{\text{Number of cubic centimeters of blood flowing through the lungs per minute}}{\text{Number of cubic centimeters of blood flowing through the lungs per minute}}$$

RESULTS

The effects of the operation, of the opening of the dura and of the trauma were not the same in all experiments. The observations on the effects of injury to the cerebrum, the cervical cord and the thoracic cord will be considered separately.

Trauma to the Cerebrum.—Ten experiments were performed in this group. Five of the animals were anesthetized by morphine, four by chloralose and one by ether. Ether anesthesia was unsatisfactory because of the enormous change which it caused in the output of the heart. The pulse rate increased in all experiments. The body temperature showed practically no change throughout the observations in the six experiments in which it was determined. There was little alteration in the oxygen content of the arterial blood. Usually the oxygen content of the mixed venous blood showed a progressive fall, and hence there was usually an increase in the arteriovenous difference.

There was little alteration in the consumption of oxygen in most of the experiments. On comparing the consumption of oxygen during the period shortly following the operative exposure of the dura with that of the control period, it was found to be the same in eight of ten instances, and to be slightly elevated in the remaining two. Immediately after opening the dura, the consumption of oxygen was practically the same as that in the control period in seven of ten instances and was slightly elevated in three. Varying degrees of trauma had no effect on the consumption of oxygen in six of ten instances; there was an increase in one experiment and a fall in three.

The exposure of the dura was associated with no change in the cardiac output in two of the ten experiments; there was an increase in the cardiac output in two instances and a decrease in six. When the dura was opened, the cardiac output remained the same as that for the control period in two experiments; it was elevated in one and decreased in seven. The fall usually consisted, in the main, of that which had been caused by the operative exposure of the dura, and the opening of the dura itself seemed to have little effect. Trauma to a cerebral hemisphere was associated with a fall in the output of the heart in seven of the experiments, with first a rise followed by a fall in two cases and by a sustained rise in one. A great deal of trauma was necessary in most instances to alter the cardiac output.

Protocol 1: Feb. 8, 1929, weight of dog, 10 Kg.; 9 a. m., 0.081 Gm. morphine; 10:40 and 11:35 a. m., control determinations; from 11:55 to 12:15, under ether anesthesia, dura of right cerebrum exposed, not opened; 12:30, 0.049 Gm. morphine; 1 p. m., forty-five minutes after operation, determinations; 1:30, dura opened with no ether; 1:55, twenty-five minutes after opening dura, determinations; 2:20, brain traumatized with finger for about five minutes; 2:45, twenty-five minutes after traumatizing brain, determinations; 3:15, fifty-five minutes after

traumatizing brain, determinations, 3 40, eighty minutes after trauma, determinations, 3.50, slight additional trauma; 4.05, fifteen minutes after additional trauma, determinations.

Exposure of the dura was associated with a decrease in the maximum blood pressure in six of the ten experiments and with no alteration in four. In three of the experiments there was a slight fall in the maximum pressure on opening the dura, but there was no appreciable alteration in the other instances. Trauma to the brain produced a fall in pressure in all experiments, but in several instances it had to be continued until the brain was badly macerated. Changes in blood pressure could be produced more readily by pressure at the base of the cerebral hemi-

spheres. It was noted that pressure in some areas at the base which were not accurately localized was associated with marked temporary elevations in the blood pressure.

The minimum blood pressure was not affected by the operative exposure of the dura in four of the experiments; in three instances it was slightly elevated, and in three it fell. After opening of the dura, the pressure fell slightly in five experiments and rose slightly in three. After traumatization of the brain, the minimum pressure fell in nine of the ten experiments.

The decline in maximum blood pressure, minimum blood pressure and cardiac output usually occurred simultaneously and to approximately the same degree. Increase in pulse rate usually preceded a decrease in the functions just mentioned.

Protocols and tables 1 and 2 give the data on individual experiments.

PROTOCOL 2: March 5, 1929, weight of dog, 10 Kg.; 9:30 a. m., 0.098 Gm. morphine; 11:20, control; from 12:05 to 12:12, left cerebrum exposed, with little loss of blood; slight ether anesthesia employed; dura not opened; 1:55, 103 minutes after operation, determinations; 2:50, three minutes after opening dura, determinations; from 3:16 to 3:19, brain traumatized; 3:21, two minutes after trauma, determinations; 3:35, blood pressure had fallen a great deal; no further trauma; determinations.

Trauma to the Cervical Cord.—Six experiments of this type were performed. Morphine was used as the anesthetic in most instances. It was found in several experiments that the dura could be exposed and opened without causing any alteration in the cardiac output or in the blood pressure. Trauma to the cervical cord produced a cessation of respirations in all experiments except one. The respiratory movements

would first become slow and then shortly stop entirely. An effort toward respiration, however, was being made by the accessory respiratory muscles, as was evidenced by movements of some of the muscles of the neck and face. The pulse became very slow and remained strong for a long period, during which tracheal insufflation was instituted.

In the one experiment in which trauma to the cervical cord did not produce immediate death, several series of determinations were made. The cardiac output was not determined before the dura was exposed, but this procedure caused no alteration in the arterial pressure. The cardiac output, the maximum blood pressure, the minimum blood pressure and the mean blood pressure declined together. The decrease in cardiac output was associated with practically no alteration in the oxygen consumption and with an increase in the arteriovenous difference in oxygen content. The results of this experiment are given in table 3.

PROTOCOL 3: Jan. 15, 1929, weight of dog, 9 Kg.; 11 a. m., 0.098 Gm. morphine; 11:30, blood pressure 120 systolic, 80 diastolic; from 11:45 to 12:15, spinal cord

in midcervical region exposed for about 3 cm., with a small loss of blood; ether anesthesia; dura not opened; 1:45, ninety minutes after exposure of dura, determinations; 2:15, dura opened; cord not traumatized; 2:20, five minutes after opening dura, determinations; 2:40, twenty-five minutes after opening dura, determinations; from 3:14 to 3:18, cord traumatized with finger; 3:26, eight minutes after trauma ended, determinations; 3:52, thirty-four minutes after trauma to cord, determinations.

Trauma to the Thoracic Cord.—Three experiments of this type were performed. Morphine was used as a narcotic. Usually the dura was exposed and opened without any fall in the arterial blood pressure or in the cardiac output. A great deal of trauma was necessary to produce a definite decrease in either the blood pressure or the output of the

heart. When an alteration of this kind was produced, the blood pressure and cardiac output fell together. There was little alteration in the consumption of oxygen. The results of an experiment are recorded in table 4.

PROTOCOL 4: Jan. 1, 1929, weight of dog, 12 Kg.; 9 a. m., 0.098 Gm. morphine; 10:50, control determinations; 12:10, ten minutes after completion of operation for exposure of cord in lower thoracic region; light ether anesthesia, dog awakening at time of observations; practically no loss of blood; dura not opened; 2:45, dura opened for a distance of 3 cm.; dog completely quiet; 2:50, determinations, five minutes after opening dura; 3:15, determinations, thirty-five minutes after opening dura; from 4:05 to 4:08, slight trauma to cord with a blunt instrument; cord not crushed; 4:12, four minutes after trauma, determinations; 4:47, thirty-nine minutes after trauma to cord, determinations; 5:15, sixty-seven minutes after trauma to cord, determinations; 5:30, cord crushed by clamp for distance of about 2.5 cm.; animal struggled little; 5:50, determinations, twenty minutes after crushing cord; 7:15 pulse 188; blood pressure 80 systolic and 64 diastolic.

COMMENT

The data presented here throw some light on the question as to whether or not shock can be produced by trauma to the central nervous system. The operation, the production of the trauma and the collection of the samples of blood for gas analyses resulted in the loss of a moderate amount of blood. The simple removal of the same amount of blood from an animal that did not have the operation and the trauma would not produce changes of the magnitude reported in this paper. The amount of blood lost is comparable to that lost in operations on the central nervous system.

Wiggers⁶ studied shock that was produced by manipulation of the intestines, by trauma to the sciatic nerve and testicle and by hemorrhage; he found that the changes in the circulatory mechanism were essentially the same. Blalock,⁷ in a study of the effects of hemorrhage, found that the changes in cardiac output preceded alterations in the mean blood pressure. Usually the maximum pressure fell and the minimum pressure rose before there was a marked reduction in the output of the heart. In the present study, there was a rise in both systolic and diastolic blood pressure, which in some instances occurred immediately after the

7. Blalock, Alfred: Mechanism and Treatment of Experimental Shock: I. Shock Following Hemorrhage, *Arch. Surg.* **15**:762 (Nov.) 1927.

trauma and lasted for a few seconds. The cardiac output could not be determined in such a short interval by the method used. After this brief initial period, in a few experiments and in all other instances, it was found that the cardiac output and the maximum and minimum blood pressure declined together. These changes were usually preceded by a definite quickening of the pulse. This is in contrast to the observation in shock produced by hemorrhage. The first change in hemorrhage, with the exception of a lowering of the volume of blood, was a vasoconstriction which caused an increase in the minimum blood pressure. These facts are evidence that vasoconstriction does not occur after injury to the central nervous system. It is also significant that the cardiac output falls tremendously after hemorrhage before the mean blood pressure falls, whereas no instance of a definite fall in cardiac output was found in these experiments with trauma without some fall in the blood pressure. In other words, after trauma to the central nervous system, there is not the critical level in the blood pressure which seems to exist in hemorrhage. This observation probably accounts for the fact that a fall in blood pressure is not as serious during operative procedures on the central nervous system as it is during or after other types of operations or after hemorrhage.

As has been stated previously, the effects of the loss of small amounts of blood cannot be ruled out in these experiments, but the fact that the changes here reported are different from those produced by hemorrhage alone indicates that hemorrhage is not the causative factor. We believe that the results obtained are the results of the trauma to the central nervous system. The rise in the minimum arterial pressure and the fall in the maximum pressure in uncomplicated hemorrhage which results in a lessening of the pulse pressure denotes the onset of a grave condition. The pulse pressure usually maintains a high level during the early stages of trauma to the nervous system, and this is probably a good prognostic sign.

In hemorrhage the blood pressure is not of paramount value as an indication of incipient shock. The blood pressure serves as a more accurate index of the condition of the circulation after trauma to the central nervous system because alterations in the blood pressure parallel other circulatory changes.

The increase in diastolic pressure after uncomplicated hemorrhage in moderate amounts is due to a contraction of the arteries in an effort to keep the arterial blood pressure at the normal level. Undoubtedly there is a different mechanism which operates after trauma to the central nervous system. It is likely that the injury causes a relaxation of the vessels of some large area, such as the splanchnic region, or perhaps of the entire body. The decline in pressure may appear quite early and

probably is not due to the accumulation of toxic products that cause capillary dilatation and increased permeability.

A decline in the blood pressure and cardiac output was found in most instances without any decrease in body temperature. This may be explained in part by the fact that dogs have sweat glands which allow for the dissipation of heat.

Trauma to the nervous system in dogs, accompanied by a decline in the arterial blood pressure and the output of the heart, may or may not be associated with a decrease in the total consumption of oxygen. Henderson, Prince and Haggard⁸ stated that metabolism is lowered in animals in which experimental shock is produced. Aub,⁹ working on cats, produced shock by trauma to the leg in some instances and by hemorrhage alone in others. He stated: "Experimental traumatic shock causes a marked fall in the rate of basal metabolism to 70 per cent of the original level. The degree of fall is dependent on the severity of the shock produced. The effect of hemorrhage is not constant. It may temporarily lower, or have no immediate effect on the metabolic rate." The observations after hemorrhage were confirmed by Blalock.⁷ Cannon¹⁰ emphasized the importance of maintaining the delivery of oxygen to the tissues and stated that most of the harm which results from the low arterial pressure and diminished volume of blood is due to the poor supply of oxygen to the tissues. It is interesting to note in these experiments that the total consumption of oxygen in several instances remained at the normal level, while the blood pressure, the output of the heart and the volume of blood were diminished. Even in instances such as those reported by Aub, in which the basal metabolism fell 30 per cent, the decline can be accounted for partially by decrease in blood flow in the "less essential organs." Gesell¹¹ studied the blood flow through the salivary gland after hemorrhage and injury to the tissues and found striking decreases in the flow. In one experiment, for example, he found that the removal of 10 per cent of the estimated volume of blood caused a decrease of 60 per cent in the flow of blood through the salivary gland. It is likely that a similar condition exists in the extremities.

The volume of the circulatory blood is certainly reduced in shock produced by all methods. Shock may be found with a normal arterial

blood pressure, normal consumption of oxygen, normal pulse rate and a normal temperature. It almost certainly cannot be produced by any method which does not cause a lowering of the cardiac output and of the oxygen content of the mixed venous blood. It is believed that this work emphasizes the futility of trying to designate by the word shock or any other term the varying conditions which result after trauma and hemorrhage. A similar mistake would be the consideration of all fevers as of one type.

SUMMARY

The effects on the pulse rate, temperature, maximum and minimum arterial blood pressures, arterial and venous oxygen content, consumption of oxygen and cardiac output were studied after (1) the operative procedure that was necessary for the exposure of the dura, (2) the opening of the dura, and (3) trauma to the central nervous system in the (*a*) cerebrum, (*b*) cervical cord and (*c*) thoracic cord.

1. In some instances the operation that was necessary for the exposure of the dura and the opening of the dura caused no decrease in the arterial blood pressure or in the cardiac output.

2. Trauma to the central nervous system caused a diminution of the maximum and minimum arterial pressure and the cardiac output.

3. The pulse rate usually increased before the blood pressure and cardiac output altered.

4. The blood pressure and the cardiac output apparently changed simultaneously.

5. The alterations in the consumption of oxygen were variable, but in the majority of instances, trauma caused no appreciable alteration from that of the control period.

6. In the majority of instances, changes in body temperature were negligible.

7. The differences in the effects of hemorrhage and trauma to the central nervous system have been stated.

THROMBO-ANGIITIS OBLITERANS

GENERAL DISTRIBUTION OF THE DISEASE*

MAURICE E. BARRON, M.D.

AND

HARRY LINENTHAL, M.D.

BOSTON

Von Winiwarter,¹ in 1878, described a case in which the arteries of a lower extremity were occluded by a chronic proliferative process arising from the intima and showed an inflammatory reaction of the walls of the vessels. He called this lesion "endarteritis obliterans."

Since then many writers have described this disease, but it was not until the studies of Buerger² in 1908 that the pathologic changes were minutely described and the disease established as a definite clinical and pathologic entity. From the time of the first description by von Winiwarter¹ to the present, there has been a tremendous amount of study and investigation of this lesion.

It is the object in this paper to direct attention to the more general distribution of the disease in contradistinction to what has previously been believed concerning it—that it is a disease involving the blood vessels of the extremities exclusively. It attacks the walls of the blood vessels, both veins and arteries, throughout the entire vascular system, the cranial, thoracic and abdominal vessels as well as the vessels of the extremities. The signs and symptoms are characteristic of the vessels involved, so that the lesion affecting the arteries of the brain may give rise to a hemiplegia, of varying degree of severity, or, should the coronary vessels be involved, the characteristic symptoms of coronary thrombosis or angina pectoris may ensue.

This study is based on thirty-four cases. Twenty-seven were observed by us, including two of hemiplegia in which a definite diagnosis of thrombo-angiitis obliterans had been made and one case of coronary thrombosis in the presence of progressive thrombo-angiitis obliterans. Seven cases were collected from the literature. We have intentionally

eliminated cases that showed gross arteriosclerotic changes in the vessels to which occlusion of the lumen could be attributed. The patients whose cases we report were under the age of 50 and had shown definite evidence of thrombo-angiitis obliterans for many years. We report these cases because they show a general distribution of the disease. We feel that this is not a large series on which to base conclusions, but we hope that this paper may stimulate further interest and observation.

REPORT OF CASES

CASE 1.—J. S., a Jew, aged 48, born in Russia, was operated on for a duodenal ulcer in 1918 when a gastro-enterostomy was done. His symptoms, however, were not relieved, and six months later he was operated on again. Shortly upon leaving the hospital after the second operation, he began to complain of severe pain in the right calf on walking and more or less constant pain and numbness in the toes of the right foot. In 1921, gangrene developed in the third toe of the right foot. He remained in a hospital in Boston for eleven weeks, when his toe was amputated. The pain in his right leg and foot, however, continued, and shortly afterward gangrene developed in the second toe. At this time, the patient entered the Beth Israel Hospital, where a diagnosis of thrombo-angiitis obliterans was made. An amputation below the knee was done. The stump seemed to heal well and the patient was sent home. Two months later, he came back to the hospital complaining of bleeding hemorrhoids. These bled profusely and produced a severe secondary anemia, which required a transfusion. The hemorrhoids were removed under local anesthesia. At this time, he began to complain of some pain, not severe, in the left calf. Pulsation in the left dorsalis pedis artery was not felt.

The patient got along well with an artificial right limb until June, 1928; then he came back to the hospital because he was unable to raise the stump of his right leg and his speech was slow and thick. On admission to the hospital, he was found to be suffering from a hemiparesis of the right side, involving the right leg and arm and also the right side of the face. The right knee jerk was exaggerated. The abdominal reflexes were abolished. The cremasteric reflex on the right could not be obtained. The blood pressure was 116 systolic and 60 diastolic. The Wassermann reaction of the blood was negative; that of the spinal fluid was negative. His heart was not enlarged. A systolic murmur was heard over the precordia. The aortic second sound was not accentuated.

The paralysis of the right side cleared rapidly. In three weeks, the patient was out of bed and got along pretty well with the support of one crutch. About six weeks after admission, he was discharged from the hospital with a slight residual paralysis.

During his stay in the hospital, the patient had considerable trouble with his left lower extremity, for which he was given sodium citrate. It may be of interest to note a decrease in the pain in the left calf after daily intravenous injections of 20 cc. of a 20 per cent solution of sodium citrate. Another fact of interest is that this patient was not a cigaret smoker; all he ever smoked was three small cigars daily.

Comment.—This patient had a number of vascular accidents. While it is true that a patient suffering from thrombo-angiitis obliterans may have duodenal ulcer, bleeding piles and cerebral thrombosis, the question arises whether all these vascular accidents might not be due to one underlying condition.

In the absence of arteriosclerosis, cardiorenal disease or hypertension, it may be reasonable to suppose that there is a relation between the thrombo-angiitis obliterans of the lower extremities, the presence of which was definitely proved, and the other vascular accidents, and that they are all of the same pathology.

That the disease at the time of writing had not yet become quiescent is shown by the fact that the patient still had intermittent claudication in the left leg and a certain amount of edema and the usual cyanosis of the left foot.

CASE 2.—M. G., a Jew, aged 45, born in Russia, had complained for about a year and a half of pain in both calves on walking, more marked in the right, and extremely severe in the right foot, particularly in the great toe. Examination at the time the pain was first noted showed no pulsation in the dorsalis pedis artery on the right, but it was definitely felt in that on the left. There was a great deal of redness and tenderness of the right toe. The patient was at another hospital for twelve weeks, where a diagnosis of thrombo-angiitis obliterans was made. The pains in his foot were most excruciating, and did not respond to any kind of treatment that was tried, including inoculation with typhoid vaccine. An ulceration of the great toe then began to develop, and an amputation of the leg was considered; however, a ganglionectomy and ramisection were performed, the second, third and fourth right lumbar sympathetic ganglions being removed. The pain stopped immediately, and the ulceration of the toe healed completely. He was discharged from the hospital feeling perfectly well; the pulsation in the dorsalis pedis artery on the right, however, could not be felt.

A few months after he left the hospital, a superficial phlebitis of the right leg developed, which subsided with moderate rest. He soon resumed his work as salesman. While in the West, one day early in August, 1928, he suddenly felt a tingling in his left arm and left leg, which lasted a few minutes. About three quarters of an hour later, he completely lost the power of his left arm and left leg and fell. He was placed on a train and sent on to his home in Boston. He was seen within twenty-four hours after the onset of his trouble. At this time, he had a complete paralysis of the left arm and left leg with a slight involvement of the left side of the face.

Examination.—The physical examination on his entrance to the Beth Israel Hospital on Aug. 10, 1928, showed complete paralysis of the left arm and left leg. Pulsations in the dorsalis pedis artery on the right were not felt, but were felt in that on the left. All the reflexes on the left were exaggerated. A positive Hoffmann's sign was elicited on the left. There was clonus of the left ankle, but no Babinski sign. Abdominal reflexes were active on both sides. There were no sensory disturbances. Examination of the fundus showed considerable tortuosity of the veins, which were rather dark, and the arteries showed a white line around the border. The results of the physical examination were otherwise negative. The heart was not enlarged; the sounds were of good quality without murmurs. The blood pressure was 110 systolic and 80 diastolic. There was no evidence of any renal disease. The Wassermann reaction of the blood was negative. An x-ray picture of the lower extremities showed "no deviation from the normal in the bones and articular surfaces," and "evidence of calcium deposits on the blood vessels around the ankle joints."

The patient felt well and recovered from the paralysis with extraordinary rapidity. A few days after his entrance to the hospital, he had obtained motion in the arm and the leg, and two weeks after entrance he was able to walk.

On August 30, the patient began to complain of pain in the right leg. Examination revealed a superficial phlebitis, characteristic of thrombo-angiitis obliterans, the so-called migrating phlebitis. About four weeks after his admission, the patient was walking, and the grip of his left arm was almost equal to that of the right.

Comment.—This man showed no clinical evidence of arteriosclerosis or cardiorenal disease; he had thrombo-angiitis obliterans with two attacks of superficial phlebitis. A complete hemiplegia developed, which cleared up within so short a time that it could not well have been due to a cerebral hemorrhage. It is interesting to note that the ganglionectomy certainly relieved his symptoms, but apparently did not stop the progress of the disease, as is evidenced by the subsequent history of phlebitis.

The condition at least suggests that the vascular lesion of the brain was similar in character to that of the vascular disease in the legs and that the hemiplegia was probably due to partial occlusion, with vascular spasm of the cerebral arteries, rather than to cerebral hemorrhage.

The fact that the x-ray picture showed evidence of a deposit of calcium in the blood vessels about the ankles is no indication that the occlusion of the blood vessels was the result of arteriosclerosis.³ It simply meant that he was approaching the age when arteriosclerotic changes begin to manifest themselves; it had nothing to do with the disease in question.

CASE 3.—J. M., a Jew, aged 46, married, born in Russia, was referred to the Beth Israel Hospital on Nov. 17, 1928, by Dr. S. A. Levine. Ten years before, the patient had had cramps in the calves when walking. This was diagnosed by Buerger as thrombo-angiitis obliterans. The condition gradually became worse; gangrene of the first two toes of the left foot set in, and one and one-half years before his admission to the Beth Israel Hospital an amputation of both toes was performed. During the few months preceding his admission, the pain in the right leg and right foot became much worse, and a marked change took place in the color of the dorsum of his foot. It was cherry red. Four weeks previous to admission, while in bed, he was suddenly taken with an agonizing pain in the chest of a constricting character, which lasted for thirty-six hours. After this, he had shortness of breath, which he had never experienced previously. On more careful questioning, it was found that for two months previous to the attack mentioned he had had similar minor pains in his chest, which were of short duration. His blood pressure, which varied from 130 to 140 systolic ordinarily, fell to 90 during the attack. Pain was entirely gone when he was last under observation, but he complained of dyspnea, especially at night. When first seen by Dr. Levine, the patient looked sick and dyspneic. His heart was considerably enlarged,

3. Brown, G. E., and Henderson, M. S.: Diagnosis and Treatment of Arterial Vascular Diseases of the Extremities, *J. Bone & Joint Surg.* 9:613 (Oct.) 1927.

and there was a definite sound of pericardial friction and some evidence of congestive failure. The patient when last seen complained of severe pain in the right foot, more particularly in the right great toe.

His other past history and the family history were negative. His wife and three children were living and well.

Examination.—The patient weighed 117 pounds (53.1 Kg.). The vital capacity of his lungs was 1,700 cc. (markedly diminished from normal). The urinalysis was negative. The blood pressure was systolic, 108; diastolic, 70. The Wassermann reaction of the blood was negative. The pupils were equal and reacted normally. The patient looked sick and dyspneic. There was no glandular enlargement. The throat was normal. The lungs showed a moderate number of moist râles at both bases; breath sounds were diminished. The heart was considerably enlarged; the measurements were 13 cm. to the left and 5 cm. to the right. There was a definite fading sound of pericardial friction over the precordia. No endocardial murmurs were heard. There was a question of gallop rhythm. No peripheral edema was observable over the shins or sacrum. No pulsations could be felt in any of the main vessels throughout both lower extremities. The first two toes of the left foot had been amputated. The dorsum of the right foot was cherry red to purple, and the toes felt cold. The radial and ulnar pulses in the upper extremities could be felt. Electrocardiographic tracings showed certain minor changes in the T-wave in lead 1 which are frequently seen in cases of coronary thrombosis. This patient had a ligation of the right popliteal vein. During the operation, the femoral artery as far as it could be felt, showed no evidence of pulsation, nor could pulsation be felt in the popliteal artery.

Comment.—This patient had had thrombo-angiitis obliterans for many years. About ten weeks previous to our study of his case early symptoms of angina pectoris developed. Four weeks previously, he definitely had an attack of coronary thrombosis. The severe pain, the preceding angina pectoris, the fall in blood pressure, the development of dyspnea, the finding of pericardial friction and the change in the electrocardiograms made this diagnosis certain. The right leg, however, when he was last seen, was becoming more painful. The case is interesting especially in that the same condition and the same sequence developed in the coronary arteries that probably were taking place in the arteries of the legs, first the intermittent spasm and finally a closure.

CASE 4 (Riesman⁴).—M. A., a married man, aged 44, a Russian manufacturer, for several years had had a good deal of pain in the epigastrium, for which he had consulted physicians and received various diagnoses, such as duodenal ulcer and that of gallstones. One day Dr. Riesman was asked to see him and found him in an attack characterized by excruciating pain in the epigastrium and profound shock, ending in eventual unconsciousness. The symptoms and physical signs were those of coronary occlusion. The patient died during the attack. On going over his records, Dr. Riesman found that the man had come to him on one occasion several years before, complaining of sciatica. On examination, he found the pulse of the dorsalis pedis artery absent and after close study was able to make a diagnosis of intermittent claudication.

4. Riesman, David: Myocardial Disease and Its Gastric Masquerades, J. A. M. A. 91:1521 (Nov. 17) 1928 (case 3).

Comment.—It was justly assumed that the intermittent attacks of abdominal pain that had led to a diagnosis of gallstones or ulcer had been due to a temporary or permanent occlusion of small branches of the coronary artery; the possibility of a true abdominal angina, an intermittent claudication of branches of the celiac axis, has also to be kept in mind.

CASE 5 (Czerna⁵).—A Polish Jew, aged 36, since the age of 20, had had recurring attacks of pain in the legs, which confined him to bed for from four to six weeks at a time. There were intervals of several years when he was free from pain. He also, at one time, had an "acute attack of heart trouble" for which he remained in bed for four weeks. At one time, paralysis developed in the right side of the face, and lasted for four weeks; at the onset of this attack he also had some difficulty with his speech. At another time, he had an attack of unconsciousness, which was diagnosed as due to a cerebral embolus. The present attack started one year before, when he suddenly began to have severe pain in the left foot and left leg. About three months before his entrance to the hospital, he had an ulcer over the right internal malleolus. A few weeks previous to admittance, he also had an attack of pain in the left arm and hand, which lasted for three weeks.

Examination.—The muscles of the right thigh and the lower part of the right leg were atrophied. Over the right internal malleolus, he had an ulcer about 1 cm. in diameter. There was no edema. The veins were markedly dilated and tortuous. Pulsation in the dorsalis pedis artery and the posterior tibials, on both sides, could not be felt, and there was no pulsation in the right femoral artery. Pulsation in the left radial artery could be felt about 5 cm. proximal to the styloid process; beyond that the artery was felt as a fibrous cord. The heart was slightly enlarged. There were no murmurs. Blood pressure was 130 systolic and 90 diastolic. The urine disclosed nothing abnormal and the Wassermann reaction of the blood was negative. He showed signs of left facial paralysis. His left knee jerk was more lively than the right. There were no sensory disturbances. He remained in the hospital for eight months. After leaving the hospital, he had an attack of severe pain in both feet, and six days later, after the pain had somewhat subsided, he became unconscious, had convulsive seizures and died.

On postmortem examination, it was found that his heart was slightly enlarged and weighed 400 Gm. The wall of the left ventricle was hypertrophied. There were some yellowish-white spots on the left auricle. On the aorta, near the origin of the coronaries, there were a few grayish-white, rough spots. The ascending branch of the left coronary, 3 cm. from the orifice, was occluded by fibrous tissue. Near the orifice of the intercostal vessels were some yellowish spots. The right external iliac and the right femoral were occluded by an organized thrombus. They felt like cords. The left femoral and popliteal arteries were also occluded. The basilar and the beginning of the posterior cerebral arteries were occluded by organized thrombi. The left radial artery about 1.5 cm. distal to the styloid process was occluded by a thrombus. There was an area of softening of the brain about the size of a pea near the corpus callosum and the upper part of the pons.

Comment.—This patient, aged 36, dated his symptoms back to the age of 20. During the progress of his illness, he had had many symp-

5. Czerna, Stephan: Arteritis Obliterans with Similar Changes in the Veins, Arch. f. inn. Med. 12:213, 1926.

toms and physical signs pointing to vascular lesions in the heart and brain as well as in the extremities. The postmortem examination yielded observations consistent with the physical signs presented during life. The lesions characteristic of thrombo-angiitis obliterans were widespread throughout the vascular tree.

CASE 6 (Perla⁶).—A man, aged 44, had begun to complain, at the age of 27, of pain in the left foot; this was followed by gangrene of a toe, which was amputated. Later the other toes of the left foot were amputated, and one year later a midtibial amputation was performed on the left leg. At the same time, he began to have trouble with his right leg, and one year later it was amputated at the upper third of the lower part. Fourteen years after the onset of his trouble, gangrene developed in the ring finger of the right hand, which was amputated. Seven months prior to Perla's observation of the patient, the stump of the left leg began to be painful. It felt cold, was dark blue and soon became gangrenous; it was amputated above the knee. On admission to the hospital at this time, the patient complained of pain in both stumps. A gangrenous patch was observed in the right stump. He suffered from a great deal of pain. Both hands also had a purplish hue and became deeply cyanotic when lowered. When the arms were raised, however, both hands rapidly became pale. The results of the physical examination were otherwise negative. The urine was normal and the Wassermann reaction of the blood was negative. The blood pressure varied between 115 systolic and 90 diastolic and 135 systolic and 92 diastolic. A few months later his right leg was reamputated at the middle of the thigh, and one year later the index finger of his left hand was amputated. One year after this, the patient suddenly had a vomiting attack, became cyanotic and died. On postmortem examination, organized canalized thrombi were found involving the arteries of all the extremities, as well as the external iliac and the left coronary artery. The probable cause of death was thrombo-angiitis obliterans with extension of the process from the iliac arteries into the aorta as far as the renal arteries. The heart weighed 470 Gm. The main left coronary artery, beginning 1.5 cm. from its orifice in the aorta, showed an organized canalized thrombus almost completely occluding the lumen for a distance of 1.5 cm. The process here resembled that in the vessels of the extremities. The right coronary artery showed no abnormalities.

Comment.—The progress of the disease in this patient apparently could not be controlled. Almost all the vessels were involved. At an early age, the patient developed thrombo-angiitis obliterans, which made itself manifest in the lower extremities. Postmortem examination revealed the characteristic lesion of the disease also in the coronary artery.

CASE 7 (Buerger⁷).—A man, aged 35, a Russian, gave a history typical of thrombo-angiitis obliterans of the left lower extremity, for which amputation was

6. Perla, David: An Analysis of Forty-One Cases of Thrombo-Angiitis Obliterans, *Surg. Gynec. Obst.* **41**:21 (July) 1925 (case 3).

7. Buerger, Leo: Concerning Vasomotor and Trophic Disturbances of Upper Extremities, with Particular Reference to Thrombo-Angiitis Obliterans, *Am. J. M. Sc.* **149**:210, 1915 (case 9).

done in 1903, and a reamputation one month later. In 1905, an ulcer developed at the inner side of the right heel. Gangrene advanced rapidly and the right leg was amputated. Five years later, the disease involved the left upper extremity. Gangrene started in his fingers, giving rise to excruciating pain. On the amputation of his forearm, both the radial and the ulnar arteries were completely occluded and showed the typical lesions of thrombo-angiitis obliterans. Four years later, in April, 1914, the patient, in a condition of stupor, was again admitted to the wards of the Mount Sinai Hospital. His speech was incoherent and there were evidences either of some cerebral lesion, or of a vascular lesion in the brain. The condition of the right hand was of particular interest. Nowhere was there any evidence of ulcer or gangrene. The skin of the right hand was dry and atrophic. The fingers had a tapering appearance. The skin had lost its elasticity, the subcutaneous tissues had withered and neither the radial nor the ulnar arteries were palpable. The brachial artery, too, gave but the slightest impression of pulsation.

Comment.—This young man had had several amputations of the lower and upper extremities because of thrombo-angiitis obliterans; signs of a vascular lesion of the brain suddenly developed. In the presence of the known diagnosis, thrombo-angiitis obliterans, and the absence of arteriosclerosis, it may be assumed that the cerebral vascular lesion was due to the progressive activity of this disease.

CASE 8 (Lewis⁸).—A man, aged 47, of German extraction, admitted to the Johns Hopkins Hospital in December, 1926, had for the last seven years had pains in both calves. The pain had increased in severity and frequency, and practically prevented him from walking. Several years after the onset of pain in his legs, the same kind of pain developed in his right forearm, so that he was unable to work. Two years previous to admission, he was operated on for varicose veins, but the pains in his legs were not relieved. The intermittent limping persisted. On examination, the radial pulse could not be palpated on the right side; the left radial pulse was felt faintly, but the arteries were not sclerosed. Both feet were purplish. The dorsalis pedis and posterior tibial arteries could not be felt. The blood pressure could not be obtained on the right arm; on the left arm, it was 136 systolic and 90 diastolic. One night, the patient suddenly became hemiplegic and died.

On postmortem examination, the most interesting condition found was that in connection with the general arterial tree. At the level of the celiac axis, the aorta suddenly became reduced in diameter, so that it measured hardly more than 1 cm. There was an old organized thrombus that totally occluded the abdominal aorta, beginning at the level of the celiac axis and extending all the way to the bifurcation. From about 5 to 8 cm. below the celiac axis there was a small, crescent shaped channel which was the only channel that passed through this portion of the aorta. When a probe was passed through the channel from above downward, the channel was found to end about 5 cm. above the bifurcation, where it communicated directly with a comparatively large branch, which left the aorta and spread out into the surrounding tissue. Below this branch, there was no lumen within the aorta. It was totally blocked by an old organized thrombus, which presented, on section, a peculiar transparent appearance. A complete blockage of the celiac axis had resulted from a comparatively fresh thrombus, which

8. Lewis, Dean: Spontaneous Gangrene of the Extremities, Arch. Surg. 15:613 (Oct.) 1927.

extended from the celiac axis into the lumen of the aorta or, perhaps, in the opposite direction. The portion of the thrombus that was in the lumen of the aorta communicated with the fresh thrombus lying between the exit of the celiac axis and the organized thrombus that filled the abdominal portion of the aorta. The beginnings of the common iliac arteries was occluded by old organized thrombi, which had many channels. The thrombosis affected the internal and external iliac arteries on both sides. The left external iliac artery, just before it became the femoral, was only partially occluded by a thrombus. This was also true of the right external iliac artery. In the femoral artery on the left side, extensive thrombotic changes were seen. None of the branches of the femoral group appeared normal.

In the right femoral region there was extensive thrombosis of the femoral artery and its branches. (All the main branches of the arch of the aorta showed sclerotic changes). A total occlusion of the second portion of the right subclavian artery was found; this extended into the axillary and brachial arteries. The right external carotid was closed by a thrombus; its point of origin from the common carotid was represented by a puckered scar. About 2.5 cm. above the bifurcation of the common carotid, the internal carotid artery was plugged by an organized thrombus, through which passed small, newly developed channels. In the skull, a similar thrombotic process filled the internal carotid at the point of anastomosis with the vessels from the opposite side.

Comment.—The most interesting observation was that, with the lesion so widespread, there was so little evidence of circulatory impairment. Postmortem examination showed to what great extent this disease can be distributed throughout the vascular system.

CASE 9 (Thomas⁹).—A Jewish physician, aged 44, in August, 1918, had a sudden attack of excruciating pain with a sense of constriction in the lower part of the chest. The patient was extremely cyanotic. His pain was so severe that it could be relieved only with $\frac{3}{4}$ grain (0.048 Gm.) of morphine. He remained in bed for ten days with a slight fever. The pulse rate varied from 100 to 120. His physician diagnosed the condition as "angina pectoris." The severity of his pain, however, the cyanosis, the elevation of temperature and the rapid pulse rate made the diagnosis of coronary thrombosis more probable. Three years later, he began to have severe pains in his hips and legs, so that he could not walk even short distances without stopping to rest.

The physical examination revealed conditions essentially normal, except that no pulsations could be felt in the dorsalis pedis, the posterior tibial and the femoral arteries on either side. A diagnosis of thrombo-angiitis obliterans was made.

Comment.—This patient presented a rather unusual clinical picture in that there was an absence of pulsations in the main arterial channels throughout both lower extremities, yet there was no evidence of gangrene. Shortly prior to the attacks of intermittent claudication, he had this severe pain in the chest, which was probably an attack of coronary thrombosis. The story is interesting in that he probably had the same

9. Thomas, H. M., Jr.: Persistent Leucocytosis in the Early Stages of Thrombo-Angiitis Obliterans, *Am. J. M. Sc.* 165:86 (June) 1923.

pathologic process and the same sequence of symptoms in the coronary arteries as in the arteries of the extremities, that is, first spasm and later complete occlusion.

CASE 10 (Telford and Stopford).¹⁰—A man, aged 40, born in England, at the age of 30 had noticed pain in the right calf on walking. Shortly after, a similar pain occurred in the left calf. The pain so increased in severity that for a period of two years he was able to walk only short distances with the aid of crutches. He then noticed that his right leg was slightly swollen and that the toes were purplish. During this time, he had a sore on the front of the ankle, which took eighteen months to heal. Two years before the period in question, however, the left leg began to get worse. The foot was "always stone cold," and a small septic focus appeared on the inner side of the great toe.

Except for a digestive trouble suggestive of duodenal ulcer, his previous condition was good. In his earlier days he had been a most enthusiastic fisherman and had spent much time wading, a habit to which he attributed his troubles.

Examination.—The right leg was much wasted from disuse, the muscle power was good and sensation was everywhere normal. The femoral pulse was normal, but the popliteal pulse was barely to be felt, and there was no pulse below this level. The left foot was dull red; there was edema about the dorsum of the foot and a small onychia of the great toe. There was no pulsation in the femoral artery or at any point below this. One night in January, 1924, this patient was seized with severe abdominal pain, and was found to be suffering from a perforative lesion, presumably of the duodenum, as he had for some time shown symptoms suggestive of duodenal ulcer. Laparotomy was done, and a large perforation of the anterior wall of the first stage of the duodenum was sutured; the operation was completed by posterior gastro-enterostomy. As far as his condition allowed, an exploration was made to ascertain the condition of the intra-abdominal vessels. No pulsation could be felt in the common, internal and external iliac arteries of the left side; these vessels were plainly felt as immobile cords.

He made an excellent recovery from the operation, but in April, 1924, ten and a half years after the onset of the disease, the whole of the left foot rapidly became gangrenous, the condition having spread from the old onychia of the great toe. A supracondylar amputation was done through the left thigh on the following day; the femoral artery at the level of the section was open and normal. The wound healed without incident. The histologic observations were characteristic of thrombo-angiitis obliterans.

Comment.—There was an opportunity to explore the abdominal vessels during life. The exploration revealed an absence of pulsation in the common internal and external iliac arteries of the left side, and these vessels were plainly felt as immobile cords. This man had a duodenal ulcer which perforated. Whether there was any relation between the duodenal ulcer and thrombo-angiitis obliterans is difficult to say, but it is of some significance that in case 1 of our series the patient also had a duodenal ulcer.

Another interesting observation is that, although the common internal and external iliac arteries of the left side were totally occluded, the

10. Telford, E. D., and Stopford, J. S. B.: *Thrombo-Angiitis Obliterans*, Brit. M. J. 2:1035, (Dec. 6) 1924.

femoral artery at the point of amputation was open. This point bears out some observations that we made in our own material—that an organized thrombus may be found in one part of an artery causing occlusion while the vessel slightly above or below this thrombus is perfectly free from obstruction; some distance either above or below this thrombus, another occlusion may be found.

In an interesting and important study, Meleny and Miller¹¹ injected an opaque solution into the vessels of extremities which had been amputated for thrombo-angiitis obliterans and clearly demonstrated the patchy appearance of the vessels. They showed that the opaque mass may fill part of a vessel, leave the artery by a collateral branch and then, by a circuitous route, appear again in the same vessel below.

FURTHER CASES FROM THE LITERATURE

In addition to the cases cited at length, we may also refer to Brown and Henderson's³ two cases of thrombo-angiitis obliterans in young men, both of whom showed evidence of coronary thrombosis.

Lemann¹² had under observation two patients with thrombo-angiitis obliterans both of whom had coronary occlusion.

Buerger, in his book on "Circulatory Disturbances of the Extremities," reported the autopsies in four cases of this disease occurring in young men. He stressed strongly the precocious arteriosclerotic changes in the blood vessels of these patients, particularly in the coronary arteries. One of the patients showed definite occlusion of the mesenteric vessels resulting in gangrene of the intestines. We have purposely not included these cases on account of the fact that there was such gross evidence of occlusion due to arteriosclerosis. However, it seems that in such young persons with a known diagnosis of thrombo-angiitis obliterans of the extremities there might be some relationship between the early atheromatous changes in the visceral vessels and the characteristic lesions of thrombo-angiitis obliterans of the vessels of the extremities.

Oppel,¹³ of Leningrad, called attention to the fact that patients with suprarenal arteriosis¹⁴ sometimes die of intestinal gangrene caused by thrombosis of the mesenteric arteries. He also reported the case of a patient who had thrombosis of the cervical arteries, which caused a hemiplegia. Some patients, he said, die of angina pectoris, and a post-

11. Meleny, F. L., and Miller, C. G.: A Contribution to the Study of Thrombo-Angiitis Obliterans, *Ann. Surg.* **81**:976, 1925.

12. Lemann, I. V.: Personal communication to the authors. The case reports are to appear in the *American Journal of Medical Sciences*.

13. Oppel, V. A.: Spontaneous Gangrene of the Extremities and Suprarenal-ectomy, *Lyon chir.* **14**:1 (Jan.-Feb.) 1927.

14. Oppel uses the term "suprarenal arteriosis" synonymously with spontaneous gangrene and thrombo-angiitis obliterans.

mortem dissection shows that the angina was caused by thrombosis of the coronary arteries. Therefore Oppel concluded that this disease is not local but generalized, and that every artery of the human body may be affected by thrombosis.

Constam¹⁵ also reported four cases of this disease occurring in the upper extremities in young men with no evident involvement of the lower extremities. Koyano¹⁶ in 125 cases found an associated involvement of the upper and the lower extremities in 30 per cent. According to Allen and Brown,¹⁷ of forty patients with definite involvement of the lower extremities twenty-four, or 60 per cent, showed on careful examination either complete or partial closure of the ulnar or radial arteries.

A patient under our observation at the time of writing, who had thrombo-angiitis obliterans, gave a history of intermittent claudication of twenty years' duration and at the time showed nothing more than an ulcer over the terminal phalanx of the left great toe, yet no pulsation in the main arterial channels could be felt throughout the entire left lower extremity. An opportunity was afforded to explore the left external iliac artery for some distance when the left femoral vein was ligated. There was absence of pulsation in the left external iliac artery as far as could be felt. In the right radial artery, the pulsation was much weaker than in the left, and the blood pressure in the left arm was 136 systolic and that in the right 110 systolic. This marked variation in blood pressure and pulsation of both radial arteries, together with the absence of pulsation from the highest point at which the external iliac artery could be felt throughout the entire lower extremity, makes it hard to believe that the disease is limited to the extremities and stops abruptly at the particular point in the external iliac artery that could be felt.

Comment.—From the review of these cases there can remain no doubt that thrombo-angiitis obliterans is a general disease that may attack any part of the vascular system. That it frequently involves the blood vessels of the brain, neck, thorax and abdomen, as well as of the extremities, is proved.

The reason that the characteristic signs and symptoms of thrombo-angiitis obliterans do not appear frequently in the upper extremities and only rarely in other parts of the body may be looked for by analogy

15. Constam, G. R.: Primary Involvement of the Upper Extremities in Thrombo-Angiitis Obliterans, *Am. J. M. Sc.* **174**:530 (Oct.) 1927.

16. Koyano, K.: A Clinical Study of 120 Cases of Thrombo-Angiitis Obliterans Among the Japanese, *Acta scholae med. univ. imp. Kioto* **4**:489, 1921-1922.

17. Allen, E. V., and Brown, G. E.: Thrombo-Angiitis Obliterans: Clinical Study of 200 Cases: Etiology, Pathology, Symptoms, Diagnosis, *Ann. Int. Med.* **1**:535 (Feb.) 1928.

in what takes place in extensive arteriosclerosis in the vascular tree; on postmortem examination in the latter case, one finds marked involvement of the vessels in the upper extremities and in the abdomen, but seldom observes arteriosclerotic gangrene in the upper extremities or lesions in the abdominal viscera. The greater demand made on the circulatory channels of the lower extremities because of static conditions may favor the more rapid development of the lesion. Moreover, the feet are more susceptible to slight injuries from deformities of the nails and from calluses, which are frequently the starting points of gangrene.

We know, moreover, that it is possible to maintain a sufficient circulation to keep up the nutritional balance of a part in the presence of occlusion of the main arterial trunk through collateral or anastomosing branches. If this is true for arteriosclerosis, it is more so for thrombo-angiitis obliterans. For we know from the work of Meleney and Miller,¹¹ of Lewis,⁸ and of Lewis and Reichert¹⁸ that collateral circulation and free anastomosis develop in inverse proportion to the extent and rapidity of the vascular occlusion. For that reason, because the process of occlusion is slower and more gradual in thrombo-angiitis obliterans, there is a tendency in this disease to produce a more liberal collateral circulation.

It might be of interest at this point to compare the symptom complex that occurs as a result of arteriosclerosis of the lower extremities with that from the same condition in the coronary vessels. The earliest symptoms in the lower extremities are usually intermittent claudication on walking a variable distance; the patient complains of severe cramp-like pains in the calves; he must stop and rest before he can continue. Later, there is occlusion of the peripheral vessels and possibly gangrene. A parallel syndrome occurs in sclerosis of the coronary arteries; the earliest symptom is a feeling of constriction through the chest or severe pain over the cardiac area. On exertion, the patient must stop, if walking, and rest before continuing. The later manifestation of coronary sclerosis is a distinct narrowing of the lumen of these vessels or complete occlusion. In thrombo-angiitis obliterans, the symptom complex is, likewise, first partial occlusion and spasm of the vessel causing intermittent claudication, and later complete occlusion. The analysis of the cases cited and the postmortem observations in some of them indicate definitely that a pathologic process similar to that which takes place in the extremities also occurs in the coronary arteries and vessels of the brain.

What we have previously stated in regard to the unusual development of the collateral circulation in the presence of thrombo-angiitis

18. Lewis, D., and Reichert, F. L.: The Collateral Circulation in Thrombo-Angiitis Obliterans, *J. A. M. A.* **87**:302 (July 31) 1926.

obliterans is also true of the blood supply to the myocardium, particularly so in the light of the important work of Gross,¹⁹ who demonstrated that a liberal anastomosis existed between the branches of the coronaries and that the coronary vessels were not terminal end arteries. This work was substantiated later by Spalteholz.²⁰ Oberhelman and LeCount²¹ drew similar conclusions from their studies. The recent work of Wearn²² further demonstrated that there is yet another channel by which the heart muscle may receive a sufficient supply of blood in the face of coronary obstruction; that is, by way of the thebesian vessels.

The question arises: Why do we not see more patients with coronary disease due to thrombo-angiitis obliterans and why has the observation not been made more frequently?

In view of the definitely established fact that the lesions of thrombo-angiitis obliterans do occur in the coronaries, as was shown by the postmortem observations in some of the cases cited, the suggestion is near at hand that the occasional cases of angina pectoris and coronary thrombosis that occur early in life without any evidence of vascular disease elsewhere, may, in some instances, at least, be due to thrombo-angiitis obliterans of the coronaries and not to arteriosclerosis.

The reason that it is not found more frequently on postmortem examination may be that the disease is characterized by a chronic course and that, as years go on, arteriosclerotic changes also take place in the vessels affected by thrombo-angiitis obliterans. The latter may be entirely overlooked in the presence of arteriosclerosis.

PATHOLOGY

From our studies of the gross pathologic changes of this disease, we have noted not infrequently that an organized thrombus may be found in one part of an artery causing occlusion and the vessel slightly above or below this thrombus be found perfectly free from any obstruction; some distance either above or below this thrombus another occlusion may be found. This would tend to show that the disease does not start from one special focus in a vessel, but rather arises at various levels, at different periods. This observation is based on the microscopic observations which, for example, as in one of our cases, show a well organized thrombus in the posterior tibial artery and a subacute lesion in the lower end of this vessel. These observations tend to indicate that this disease is disseminated by the blood stream.

It is probable that the disease attacks the larger vessels first, then, in the late stages, obliterates the arterioles and capillaries. This is shown by the fact that gangrene does not occur, as a general rule, until late in the disease. We know from the studies of Meleney and Miller²¹ and the observations of Lewis⁸ that there is a vigorous attempt at the formation of a collateral circulation to compensate for the occlusion of the larger vessels. It would be necessary, therefore, for the smaller arterioles and capillaries to hypertrophy and dilate to take care of this circulation; it is not unusual for this disease to exist for many years with no evidence of impairment of the circulation, although pulsation in the dorsalis pedis and posterior tibial arteries is absent. This points out that the circulation is taken on by the small arterioles, and that for some unknown reason the larger vessels suffer most, although some of the smaller vessels no doubt are also attacked late in the disease.

The collateral circulation in this disease evidently plays the most important rôle, and the ability of the arteries to make and produce new and larger collaterals often is the deciding factor as to whether or not the patient will lose a member. The mechanism of the formation of collateral circulation is not altogether obvious or easily explained. It is a remarkable phenomenon that the main arterial channels become totally occluded without the part becoming gangrenous. Clinically, it is well recognized that with occlusion of the main vessels the collateral circulation has taken the place of the main arteries. Bolognesi²³ performed experiments to determine the effect of ligating the external iliac artery in dogs. He found that the gluteal branches of the iliac artery, and especially those of the inferior or ischiatic gluteal artery, took part in the formation of the collateral circulation, becoming larger and richer in branches. These branches anastomosed fully with the femoral branches. Bernheim and Sachs,²⁴ in studies on the collateral circulation of the lower extremities of patients examined post mortem, found that the circulation to the extremities, even though the femoral artery was occluded above the origin of the profunda femoris, could be taken care of by way of the gluteal arteries in the presence of profound arterial disease. They observed in cases in which this condition existed that the gluteal vessels grew much larger and that they offered a direct line of blood flow to the tissues of the lower part of the leg and foot through the branches that run along with the sciatic nerve. In normal limbs these branches were almost invisible. That this can be accomplished is evidenced in a case reported by Dumas and Ravault,²⁵ in which the

25. Dumas, A., and Ravault, P.: *Physiologic and Histologic Investigations on the Circulatory Conditions in the Left Leg, the Femoral Artery of Which Had Been Ligated in 1870*, *Lyon chir.* **24**:387 (July-Aug.) 1927.

23. Bolognesi, quoted by Buerger (footnote 27).

24. Bernheim, B. M., and Sachs, L.: *Notes on the Collateral Circulation in Blood Vessel Diseases of the Lower Extremities*, *Ann. Surg.* **86**:417 (Sept.) 1927.

femoral artery had been ligated in the upper part of Scarpa's triangle fifty-six years before. The patient was a man who had been wounded in the left leg by a bursting shell in the Franco-Prussian war of 1870. He was examined prior to his death, which occurred on Nov. 21, 1926. There was no evidence of vascular disturbance at that time. At autopsy, it was found that an adequate collateral circulation had been established, so that the femoral artery shortly below the ligature was of normal caliber and the popliteal, anterior and posterior tibial arteries were the same on one side as on the other.

The veins in thrombo-angiitis obliterans present a condition similar to that of the arteries. Some authors² stated that about 30 per cent of their patients showed a superficial phlebitis; occasionally one sees a deep phlebitis that is characterized by more or less edema, which some investigators²⁶ use as a sort of indicator as to whether an amputation should be done above or below the knee. A superficial phlebitis developed in one of our patients while he was in the hospital (case 2). This was probably the condition that Buerger²⁷ referred to as migrating phlebitis.

Pathologic Histology.—The pathologic changes are characteristic and certainly indicate that the initial process is inflammatory. One first notices in a vein a fresh clot made up of polymorphonuclear leukocytes, lymphocytes, mononuclear leukocytes, wandering cells and red corpuscles. As the lesion progresses, foreign body giant cells are seen. This phase is present in veins in which superficial phlebitis has occurred. Attention was directed to these foreign body giant cells first by Buerger.²⁸ The inflammatory cells soon invade the intima, media and adventitia, so that in the process of healing the vein, artery and nerve are closely bound together by the newly formed inflammatory tissue. This tissue soon becomes well organized, and it is with difficulty that the vein, artery and nerve are separated. This process appears to be a phase of a defense reaction that occurs in inflammation and is really a reparative process.

Since it has been proved¹⁷ that there are no changes in the blood to cause the formation of a clot or thrombus, it is fair to assume that the clot is due to trauma to the inner wall of the vessel. As this characteristic clot, made up of fibrin, polymorphonuclear leukocytes, wandering cells, mononuclear leukocytes and giant cells, begins to organize, strands of fibrous tissue arise from the periphery made up of young connective tissue cells, mostly fibroblasts. This process goes on until there is

26. Allen, E. V., and Meyerding, H. W.: *Surgical Procedure in Obliterative Vascular Disease (Thrombo-Angiitis Obliterans): A Report of 45 Cases*, Surg. Gynec. Obst. **44**:260, 1928.

28. Buerger (footnote 27, p. 320).

complete organization of the clot. In the process of the connective tissue change there are formed new small blood vessels lined by a single layer of endothelium and somewhat similar to the capillaries in healed or healing scar tissue. The pathologic picture is entirely that of an inflammatory process with the characteristic picture of healing. This process keeps repeating itself in various vessels at various levels and at different times, so that the condition is characterized by chronicity, and it is this chronic inflammatory process that slowly occludes the vessels. It has aptly been described, therefore, as a race between the formation of a collateral circulation and the occlusion in the main arterial channels. That this process is characterized by chronicity is proved by the fact that some patients with this disease have dated their symptoms back twenty years. We had one patient in our series who was positive that he had had symptoms of intermittent claudication for fully twenty years before the onset of the trophic disturbance.

SUMMARY

This study covered thirty-four cases of thrombo-angiitis obliterans; twenty-seven cases came under our own observation and seven were collected from the literature. All the cases occurred in persons under 50 years of age, who had had the disease for many years previous to the manifestations of definite nutritional disturbance. None of the patients, therefore, were of the "arteriosclerotic age" when the disease started. In the postmortem examinations which we collected, in which evidence of arteriosclerosis was found, the arteriosclerotic process was obviously not responsible for the condition, but had been superimposed on the long standing thrombo-angiitis obliterans.

An analysis of our material shows that the disease is of a slow, insidious onset, and of many years' duration. The vessels involved are slowly occluded and, owing to this slow occlusion, there is an opportunity for collateral circulation to be established. This explains the fact that the nutrition of the part supplied by the occluded vessel is maintained, and a patient may go on for many years without nutritional disturbance of the parts involved. We have also seen that the process in the arterial tree does not spread by extension from a single focus, but may occur at different levels in an artery and in various vessels at different periods.

Above all, the analysis of our cases, and of those collected from the literature in which necropsies were performed, demonstrates that this disease is not confined to vessels of the extremities, as is generally accepted, but is a generalized disease that may affect any part of the arterial tree, including the coronary arteries, the abdominal arteries and the arteries of the brain.

CONGENITAL DEFORMITIES

Congenital Dislocation of the Hip.—MacAusland¹ reviewed the history of the operative treatment of congenital dislocation of the hip. According to him, the patients who should receive operative treatment are: (1) children from 4 to 8 years of age, in whom one or two closed manipulations have failed; (2) children over 8 years of age, and (3) adults with marked deformity or arthritic symptoms. The choice of operation depends on the existing deformity and to some extent on the age of the patient. Simple replacement of the head into the acetabulum, or some form of reconstruction operation with or without the formation of a shelf, or arthrodesis are the procedures one has at one's disposal. The author describes in detail his operative technic and the postoperative care of the patient.

NUTRITIONAL DISTURBANCES

Activated Ergosterol.—An editorial in *The Journal of the American Medical Association*² says that recent studies of Rosenheim and Web-

* Submitted for publication, Sept. 12, 1929.

* This Report of Progress is based on a review of 238 articles selected from 390 titles dealing with orthopedic surgery appearing in medical literature between Feb. 15, 1929, and June 1, 1929. Only those papers which seem to represent progress have been selected for note and comment.

1. MacAusland, W. R.: *Surg. Gynec. Obst.* 47:697 (Nov.) 1928.

2. Editorial: The Precursor of Vitamin D: Ergosterol, *J. A. M. A.* 91: 1110 (Oct. 13) 1928.

ster in London make the position of ergosterol as a parent substance of vitamin D appear unique. They have presented evidence which strengthens the assumption that only a molecular structure such as that possessed by ergosterol enables an esterol to be photochemically converted into vitamin D, and confirms the evidence already available for the view that ergosterol is the specific parent substance of vitamin D. Fortunately, the substance is obtainable with comparative ease from natural sources, so that there need be no limitations to its availability for therapeutic use if this is finally established on a sound basis.

Karelitz³ discussed the value of ergosterol, a substance formerly isolated from mushrooms, ergot and yeast, when activated by a magnesium spark of a mercury vapor quartz lamp. He cited evidence to prove that it is 20,000 times as effective as cod liver oil in combating rickets.

Hess, Bills and Honeywell,⁴ studying the variability of the antirachitic potency of cod liver oil, found that contrary to current opinion, this varies inversely with the amount of oil in the livers. From extremely "poor" livers, oil was extracted which was 200 times more potent than high grade cod liver oil and far more potent than any oil heretofore assayed. The oil from livers of individual cod may vary 1,000 times in their antirachitic value.

Renal Rickets.—Kellet⁵ reported a case of renal rickets in which the inorganic phosphorus in the blood was below normal (3.82 mg. per hundred cubic centimeters). The blood urea was 158 mg. and the calcium 10.4 mg. It has been suggested that the bone changes in renal rickets are due to an increased retention of phosphorus because of the failure of the kidney to excrete phosphorus. This case appears to refute this view. Kellet reported benefit in this case from ultraviolet therapy, whereas in most cases of renal rickets the patients are made worse by actinotherapy.

DISTURBANCES OF GROWTH

Displacement of the Upper Femoral Epiphysis.—In a review of twenty-seven cases of displaced upper femoral epiphysis, Badgley⁶ expressed the belief that at adolescence there is a change in the anatomic relationship of the head to the neck of the femur, and that there may be a thinning of the periosteum at the time of puberty, as pointed out by Key. These factors plus obesity and rapid growth, which are char-

acteristic of these patients, are important. The endocrine dysfunction is, he thinks, of little significance. The necessity of early treatment is emphasized. In the preslip stage he advised a plaster spica with the hip in abduction and internal rotation for six weeks and then the use of a walking caliper. The cases in which displacement has occurred recently require the Whitman manipulation, a plaster spica for five weeks, at the end of which time physiotherapy is started. At the end of eight weeks, a splint is given and the patient allowed to walk. In cases in which the epiphysis has been displaced as long as four months, Badgley would employ the curved osteotomy of Wilson. In young adults in whom healing has occurred the Whitman reconstruction operation is required, while in older patients fusion seems the best method of treatment.

[ED. NOTE.—Obesity is not always a characteristic of this condition, and we are not prepared to say that endocrine dysfunction is of little significance. As yet we know too little of this condition to make such statements.]

Achondroplasia.—Warner⁷ described and gave illustrations of twins, aged 10½ years, one of whom was an achondroplastic dwarf and the other a normal child. He argued from this that achondroplasia is an inherited variation and is not due to any maternal infection or influence.

VASCULAR DISEASES

Thrombo-Angiitis Obliterans.—Allen and Smithwick⁸ reported their results in twenty-five patients with peripheral vascular disease, treated by foreign protein shock. Two of the cases were undoubtedly of vasomotor origin; thirteen were of presenile gangrene, clinically thromboangiitis obliterans; six were of arteriosclerotic gangrene, including those with associated diabetes; and four were unclassified. Nineteen patients were admitted with ulceration, only six had pulsating vessels, and nineteen were completely disabled. The number of treatments varied from one to fifteen over periods varying from three weeks to fifteen months, without deleterious effect on the patient. Of the nineteen patients entering with complete disability, five had major amputations and are included in the group of seven patients considered as unrelieved. Twelve of the nineteen patients with complete disability have been able to return to their former work. Nonspecific foreign protein (typhoid vaccine given intravenously) gives a definite reaction much like that observed following periarterial sympathectomy with a definite relief from pain and a beneficial change in the appearance of the lesions. The reaction can be repeated at intervals of seven days

7. Warner, Allan: Brit. M. J. 2:983 (Dec. 1) 1928.

or more with subsequent healing of the ulcerations. The treatment should be combined with proper hygiene and minor surgical operations when necessary, as it enhances the safety of such procedures.

The end-results in ninety periarterial sympathectomies were reported by Muller.⁹ In arteriosclerotic patients twelve operations were performed, two of these being relieved from pain. In no cases of arteriosclerosis was gangrene checked by sympathectomy. Seventeen operations were performed for thrombo-angiitis obliterans. Two of these were followed by definite improvement. Pain was relieved, but no increase in the circulation was found. The operation was performed in three cases of Raynaud's disease with relief from symptoms in two of the cases. The author expressed the belief that the operation is of particular value in chronic ulcers of the extremities which have not yielded to the usual therapeutic measures.

Archibald¹⁰ found that pain from arterial disease of organic origin was not relieved by periarterial sympathectomy in more than half his cases. Ramisection was necessary in some to relieve pain.

Philips¹¹ reported a number of cases of neurocirculatory disease in which roentgen treatment was given. He stated that irradiation given over the spinal segments controlling the affected parts overcomes an overirritated status of the sympathetic ganglions. Relief from pain may occur immediately or several weeks later, followed by improvement in the circulation.

[ED. NOTE.—These reports are significant in that they show the widespread interest in conservative measures as against amputations in vascular diseases of the extremities. The last report is of an untried field, as far as we are aware, and should be repeated by other roentgen therapists.]

NEUROLOGIC CONDITIONS

Traumatic Ulnar Neuritis.—Platt¹² divided ulnar neuritis into the following clinical groups:

1. Primary neuritis resulting from contusions of the nerve or from supracondylar fracture or dislocations of the elbow.
2. Secondary neuritis complicating fractures of the lower end of the humerus or dislocations of the elbow.
3. Delayed neuritis, a sequel to external condyle fractures or caused by recurrent dislocation of the nerve.

In the milder forms of neuritis, resting the nerve in a relaxed position usually suffices; but in the severe form, the operative treatment

9. Muller, G. P.: *Ann. Surg.* 88:474 (Sept.) 1928.

10. Archibald, E.: *Ann. Surg.* 88:499 (Sept.) 1928.

11. Philips, H. B.: *M. J. & Rec.* 128:559 (Dec. 5) 1928.

12. Platt, Harry: *Surg. Gynec. Obst.* 47:822 (Dec.) 1928.

is usually indicated. The technic of anterior transposition of the nerve is described in detail. Special emphasis is placed on preservation of the small branches of the nerve and its blood supply, and on careful fixation and protection of the nerve in its transplanted position.

Surgery of the Sympathetic System.—Leriche¹³ concluded from his observations that the sympathetic nervous system acts like a vast sensory cistern with reflex associations everywhere. Every section of a sympathetic chain is followed by active vasodilatation that is more or less lasting. Paresis of vessels never occurs. Section, also, is always followed by cicatricial neuroma. The author reports the results in 400 cases of ganglionectomy, ramisection and arterial sympathectomy. Gratifying results are reported in the neuralgias following severe injuries or amputations of limbs and in chronic ulcers.

Von Lackum¹⁴ found no reason to withdraw his statement of 1926 that "there is no longer any doubt as to the efficacy of sympathetic ramisection in certain cases of spastic paralysis." Fifty-four lumbar and ten cervical ramisections have been performed. Good results can be obtained only in patients with the best mentality. Von Lackum felt that this procedure offers an effective means of relief in many cases of spastic paralysis in children.

TUBERCULOSIS

Roentgen Diagnosis.—Ghormley and Bradley,¹⁵ who believe that the study of a single roentgenogram of a tuberculous spine is of interest from a diagnostic standpoint, but from a prognostic standpoint is of much less value than a series of roentgenograms on the same patient, gave the result of their study of seventy such pictures taken at the New England Peabody Home for Crippled Children. These pictures were taken at four month intervals over a period of from two to five years or more. The patients have for the most part been treated by conservative methods—recumbency during the early stages of the disease, combined with heliotherapy, fresh air and the usual modern requisites in good general care of tuberculous patients. These estimates would therefore probably vary somewhat in a series of cases in which operation had been performed.

From this study the writers concluded that:

1. Calcification in a lesion does not necessarily mean satisfactory healing.

13. Leriche, R.: *Ann. Surg.* 88:449 (Sept.) 1928.

14. Von Lackum, H. LeRoy: *Sympathetic Ramisection in Spastic Paralysis*, *J. A. M. A.* 92:139 (Jan. 12) 1929.

15. Ghormley, Ralph K., and Bradley, John I.: *J. Bone & Joint Surg.* 10:796 (Oct.) 1928.

2. Clearing or reestablishment of bony detail is a much better indication of healing.

3. Bony fusion or bony block is a favorable sign.

4. Decrease in the size of the abscess is a favorable sign, while increase in the size of the abscess is decidedly an unfavorable sign.

5. Paravertebral abscesses accompanying dorsal Pott's disease are dangerous in that they cause a much wider destruction than the original lesion. A mechanical pulsating force must play a part in their production.

6. It is suggested that early eradication of such abscesses might be attempted, but the danger of establishing a permanent sinus is serious.

Treatment.—Clavelin and Sicard¹⁶ advocated the use of intravenous administration of calcium chloride followed immediately by ultraviolet irradiation. This was suggested to them by the work of Weill and Guillaumin on calcium fixation. They have worked out a definite dosage and plan of treatment, and feel that they have had favorable results in twenty-eight cases.

POLIOMYELITIS

Use of Convalescent Serum.—According to Aycock, Luther and Kramer,¹⁷ the rationale of giving convalescent serum in poliomyelitis is based on three facts:

1. One attack of poliomyelitis apparently confers immunity from the disease.

2. The blood serum of human beings and of monkeys who have had the disease neutralizes the virus.

3. Convalescent serum when tested experimentally exerts a protective action against the virus.

The blood, after fever and muscle tenderness have subsided, is collected into a special bottle (from 400 to 500 cc. from adults and from 200 to 300 cc. from children). It is then incubated for one hour at 37 C., and the serum is drawn off into an aspirating bottle. The serum is given both intraspinally and intravenously. Twenty cubic centimeters of the spinal fluid is withdrawn, and the same amount of serum is introduced into the spinal canal; following this, 60 cc. of the serum is given intravenously. The intraspinal dose is repeated the following day, and if the fever persists, the intravenous dose may again be given. Reactions are frequent but usually not severe.

Tendon Transplantations.—Naughton Dunn,¹⁸ in his presidential address to the orthopedic section of the Royal Society of Medicine,

16. Clavelin and Sicard, André: Presse méd. 36:227 (Feb. 22) 1928.

17. Aycock, W. L.; Luther, Elliott H., and Kramer, S. D.: Technic of Convalescent Serum Therapy in Poliomyelitis, J. A. M. A. 92:385 (Feb. 2) 1929.

18. Dunn, Naughton: Proc. Roy. Soc. Med. 22:243 (Dec.) 1928.

London, on the surgery of the muscles and tendons in relation to infantile paralysis, emphasized the fact that division of tendons and muscles is seldom necessary for the correction of deformity. In Dunn's opinion, no tendon should be divided or lengthened unless the surgeon is satisfied, as a result of his experience, that (1) correction of the deformity will improve function; (2) elongation or division of tendons is necessary to correct that deformity, and (3) the power of the shortened muscle or tendon cannot be utilized by tendon transplantation at the time of the operation. Dunn quoted flexion deformity of the hip to illustrate this axiom. The operative correction for flexion deformity of the hip joint that is commonly advised weakens the tensor fascia femoris and the gluteus medius; and yet no splintage can mask the limp resulting from paralysis of the gluteus medius, and Legg's operation of transplanting the tensor fascia femoris is the usual operation recommended to replace its function. Dunn therefore strongly urged the gradual correction of flexion contracture of the hip, thereby preserving muscles that might be badly needed for transplantation. Dunn stated that the successful transference of muscle power to a new insertion, given a good surgical technic, is mainly dependent on the recognition of the group action of muscles. In the foot, for example, there are for practical purposes only two groups of muscles: (1) the anterior tibial, in action in dorsiflexion of the foot; (2) the peroneal and posterior tibial muscles, associated in action with the tendo achillis in plantar flexion. Any of the anterior tibial muscles can successfully replace one another, but no tendon from the peroneal or posterior tibial group will effectively replace the loss of active dorsiflexion. In the upper limb where the action of individual muscles is more specialized, reeducation of an individual tendon to act apart from its group is more practicable. In the technic of transplantation, Dunn expressed the belief that the important factor is the degree of tension under which the tendon is sutured. The method of attachment—whether to bone periosteum or tendon—and the preservation of the tendon sheath, he considers of minor importance. For weakness of the tibialis anticus, Dunn performs the operation he calls "tendon fusion." All the anterior tibial tendons above the ankle are sutured together, the tension on individual tendons varying according to the previous tendency to inversion or eversion of the foot. While recognizing tendon transplantation as helpful, Dunn expressed the belief that it does not by itself produce spectacular success and that joint fusions are frequently needed in addition.

[ED. NOTE.—Naughton Dunn's observations on lengthening muscles in infantile paralysis are well taken.]

PYOGENIC INFECTIONS

Osteomyelitis.—Phemister,¹⁹ writing on the unusual forms of osteomyelitis, listed sclerosing osteomyelitis, localized diaphyseal osteomyelitis, nonsuppurative or fibrous osteomyelitis, chronic hemorrhagic osteomyelitis and osteitis fibrosa cystica. In sclerosing osteomyelitis, there is a wide diffusion of the infection without necrosis. Pain of varying intensity is the only symptom, and the patient is usually relieved by opening the sclerosed bone. Localized osteomyelitis in the shaft may be acute or chronic; pus is found only very early, and later the necrotic tissue is replaced by fibrous tissue. Areas of nonsuppurative osteomyelitis develop rather silently and are often mistaken for neoplasms. In chronic hemorrhagic osteomyelitis, the diseased tissue is stained brown from the blood pigments. It runs a chronic mild course, and the walls of the diseased area show the signs of an inflammatory process. Osteitis fibrosa cystica may be single or multiple and usually appears during the growing period. The walls of such cysts are definitely inflammatory. It is often difficult to differentiate such tissue from benign giant cell tumor.

ARTHRITIS

The Synovial Fluid in Arthritis.—Forkner, Shands and Poston²⁰ studied the bacteriology and cytology of the synovial fluid in sixty-three cases of chronic arthritis. Of these fifty-two were infectious, nine hypertrophic and two both infectious and hypertrophic arthritis. Organisms were recovered in fourteen cases, eleven of these being *Streptococcus viridans*, two the gonococcus and one *Staphylococcus aureus*. Bacteriologic examination of the regional lymph nodes gave positive cultures in 48 per cent. The cells in the synovial fluids of thirty-three patients were studied by the supravital technic. The polymorphonuclear neutrophils were increased in all cases, when organisms were recovered from the fluid. In synovial fluids in which no organisms were obtained, the monocytes and lymphocytes gave higher counts.

Deformity of Knee in Arthritis.—Swaim²¹ pointed out that the commonest deformity of the knee in arthritis is flexion and subluxation with outward rotation. This deformity presents a grave problem in the plan of reconstruction of the chronic arthritic patient as, no matter what procedures one may use—conservative stretching, manipulation or operation—only rarely is the knee a complete functional success. Flexion deformities can be prevented early in the disease and so simply that it can be done by any one. Swaim believed that if more care

20. Forkner, C. E.; Shands, A. R., and Poston, M. A.: Synovial Fluid in Chronic Arthritis, Arch. Int. Med. 42:675 (Nov.) 1928.

21. Swaim, Loring T.: J. Bone & Joint Surg. 10:742 (Oct.) 1928.

were exercised in the beginning of the active arthritis to foresee and prevent this one deformity, most patients with chronic arthritis would be on their feet much earlier than at the present time is possible. These deformities can be prevented by the use of properly applied plaster casts which should be bivalved and used at night and supplemented during the day with active exercise or a cuff with a heavy elastic band applied to the upper end of the tibia attached to a Balkan frame which takes away the mechanical force that causes the deformity.

MISCELLANEOUS

Fundamental Conceptions in the Understanding of Pathologic Change in the Bone.—Leriche and Policard²² discussed the four fundamental principles which in their opinion must henceforth govern all investigations of pathologic change in the bone.

1. Bone tissue must be considered as a storehouse of mineral matters (subject to the fluctuations of the circulation). A large part of pathologic change in the bone must be regarded as resulting from anomalies or derangements of the mineral reserve function. In order to understand this it is essential to know by what physiologic process the mineral reserves that constitute bone are built up or torn down. The authors believe that variation in the blood supply plays a large part in causing withdrawal of calcium. By experiment, they have been able to demonstrate that increase of the circulatory activity in the region of a bone is followed by rarefaction of that bone, e. g., by ramisection or periarterial sympathectomy there is produced an intense vasodilatation with decalcification of the bone. Since active vasodilatation produces an excessive withdrawal of mineral matter from the bone, they conclude: (1) that active vasodilatation is the physiologic mechanism employed by the organism where it needs calcium; (2) that the organism when it needs mineral salts extracts them from the reserve supply by waves of vasodilating nerve impulses and (3) that all diseases either general or local which provoke active vasodilatation must cause decalcification of the bones in that region. They point to the phenomena of decalcification that are observed in pregnancy, in phosphate poisoning and after traumatism as confirming these hypotheses. They also consider such lesions as Kienbock's disease, Kohler's disease and tarsal scaphoiditis as of vasomotor origin, characterized by a moderate rarefaction, spontaneously curable but with dysharmonic-osteogenic processes of repair.

2. The laws of osteogenic reconstruction in the adult govern anatomically the evolution of diseases of bone.

22. Leriche, R., and Policard, A.: Presse méd. 36:1282 (Oct. 10) 1928.

According to the authors, the fundamental principle is that at the beginning of every process of ossification there is produced an active hyperemia, acting simultaneously on the bone and on the adjacent soft tissues. This provokes a rarefaction of the former and an edema of the latter. The rarefaction sets free mineral salts, but as the ability of the blood to transport calcium is fixed at a constant, these salts become deposited in the adjacent soft tissues which have been prepared by the edema for participation in the reparative process. The same process applies to pathologic ossification whether resulting from infection or not.

3. Bone not only is a storehouse for minerals, but is also a hemato-poietic organ.

According to the authors, the bone marrow has nothing to do with the phenomena of ossification or with the life process of bone. The reactions of bone and of the bone marrow are entirely independent.

4. The mechanism of growth in length of bone is purely of cartilaginous character.

The authors stated the belief that growth in length is bound up with a balance between two phenomena of inverse character which follow each other without ever stopping: the growth of cartilage and its destruction by the bone. If the cartilage cells cease to multiply, growth stops. If the cartilage fails to obtain nourishment, ossification does not take place and again growth stops. The cartilage is nourished by imbibition; its diseases are only trophic disturbances. Because of the absence of blood vessels, the cartilage is only affected by means of its exchanges even in infection and inflammation. Finally, the life and the death of the cartilage are regulated by endocrine influences. All diseases of growth of bone and the dystrophies of the epiphyseal cartilage ought to be studied in the light of these considerations.

[ED. NOTE.—Leriche and Pollicard have for a long time been profound students and active experimental investigators of the physiology of bone. The views expressed in the foregoing paragraphs represent a crystallization of ideas which have been previously expressed at greater length and more detail in book form. They support the physioclinical theory of ossification as contrasted with the osteoblastic cellular theory. While many of their ideas are purely speculative and their conclusions open to question, every one who is familiar with their work will admit its scholarly quality and its background of studious investigation and careful observation. All physicians who are interested in bone surgery should read their interesting and thought provoking book, *The Physiology of Bone*.²³]

23. Leriche, R., and Pollicard, A.: *The Normal and Pathological Physiology of Bone: Its Problems*. Translated by Sherwood Moore and J. Albert Key, St. Louis, C. V. Mosby & Company, 1928, pp. 236.

Myofascitis.—Albee²⁴ defined myofascitis as a local manifestation of a general toxic condition, evidenced by a low-grade inflammation or toxic involvement of the muscles and fasciae, the symptoms predominating at the fascial insertions of muscle to bone. He has found it a prevalent condition and considers it a frequent cause of backache often misdiagnosed as sacro-iliac strain, lumbago, sciatica and muscular rheumatism. In his experience the evidence has indicated the colon as the source of the toxic absorption in 90 per cent of the patients, and the teeth, tonsils, sinuses, and gallbladder in the remaining 10 per cent. He has obtained striking relief of symptoms by removal of the toxic absorption from the colon, often in patients who had been entirely unrelieved by mechanical and supportive treatment of the spine.

[ED. NOTE.—Myofascitis as described by Albee may exist, but its presence is difficult to prove. Unfortunately, there is scarcely ever any chance of investigating the pathologic changes at necropsy. In cases such as these, it is almost impossible to rule out a mild toxic or infectious arthritis of the spine in a stage too early to show proliferative bone changes by roentgen examination. Measures susceptible of relieving the one ought also to benefit the other. Whether we call it myofascitis or arthritis, we can at least agree on the necessity of removing foci of infection and eliminating intestinal absorption in many cases of painful back.]

Volkman's Ischemia.—Robert Jones²⁵ clinical experience agrees with the experimental observations of Brooks and Jepson that venous obstruction is the chief causative factor in the production of Volkman's ischemia. The pressure causing the obstruction may come from without (splints or bandages of a too flexed elbow) or from within (unreduced displacement of bones and subfascial hematoma). It is Jones' opinion that ischemic contracture might occur in spite of every precaution, but nevertheless the best treatment is prevention. The prophylactic measures which he advises and which have been successful in preventing the development of any instance of ischemia in his own practice are the following:

1. Reduction of dislocations and displaced bones as soon as possible. He does not advocate leaving unreduced a supracondylar fracture for several days in order to avoid ischemia. His method of reduction has been as follows: "I first extend the arm, supinating and pulling it at the same time. While the thumb is placed on the upper fragment the extended and stretched elbow should be flexed. This usually and without difficulty gives a complete reduction."

24. Albee, Fred H.: *Myofascitis from Orthopedic Standpoint*, J. A. M. A. 91:1364 (Nov. 3) 1928.

25. Jones, Robert: *Brit. M. J.* 2:639 (Oct. 13) 1928.

2. Using no force in flexing the elbow. No force should be necessary; if the arm does not flex easily, it is suggestive of blocking due to displaced fragments.

3. Avoidance of circular compression.

4. Avoidance of all splints.

The wrist is slung in a collar and cuff sling under the chin. Whether or not there is swelling, it is a mistake to bandage the arm to the forearm or the elbow to the side.

5. For the first few days, critical observation of all fractures about the elbow.

For treatment of the fully developed condition, the author has for years used nothing but his own previously described method of gradual stretching, and he has often obtained good results by this method in patients who had been subjected to operation previously without success. In his experience, operative treatment has not been helpful; and he warns against bone resections, tenoplasties, myotomies and tenotomies.

[ED. NOTE.—Robert Jones first wrote on Volkmann's ischemic paralysis in 1908. Now, twenty years later, he has given his present views on the subject in a brief paper. No abstract can do justice to this paper, in which every conclusion and suggestion are based on a lifetime of experience.]

Bailey²⁶ stated that he has transplanted the internal epicondyle of the humerus by suturing it into a subperiosteal bed one third of the way down the shaft of the ulna for the relief of Volkmann's ischemia. Three weeks after the operation, the fingers could be completely extended. At the end of seven months, the patient had recovered almost perfect function in the limb. The operation was performed four months after the onset of the ischemia, which followed a supracondylar fracture. Massage and splintage had been tried in the interval, without any appreciable improvement.

Spontaneous Dislocations of Hip Joint During Early Life.—Hart²⁷ analyzed twenty-eight cases of spontaneous dislocation of the hip in children. He found that sixteen followed a metastatic septic arthritis, four were due to poliomyelitis, four to spastic paralysis and four resulted from tuberculosis and chronic arthritis. He considered that the essential factor in all cases is a muscular imbalance. Prevention is the best form of treatment, and to this end it is necessary to keep the hip from assuming the adducted, flexed and inwardly rotated position. Constant traction, if properly applied, is an effective therapeutic measure.

"*Riders' Leg.*"—Writing of "riders' leg," Winn²⁸ stated that he has encountered forty-two cases of this injury at the Cavalry school during the past two years. It is of great economic importance, being one of the chief causes of inability to ride among officers. "Riders' leg" is rare among enlisted men who use the McClennan type of saddle with long stirrups. The officers use a flat saddle with short stirrups. The cause is a severe strain of the adductor muscle group. The muscles involved are the pectineus, adductor brevis, adductor longus and adductor magnus. The author has never been able to demonstrate gross periosteal evulsion. The injury in all cases observed followed sudden exertion of the muscles due to an unexpected movement of the horse. The symptoms are sudden severe pain in the thigh, gradually becoming so severe that further riding is impossible. Pain recurs with attempted adduction or on walking with a long stride. Acute tenderness is found over the upper portion of the adductor longus. In some cases, ecchymosis is noticed in the pubic region. In most instances, recovery takes place in from a few days to two weeks. The injury, however, predisposes to further strains of the adductors. In recurrent cases, several months are sometimes required for recovery. Treatment consists in rest and the application of heat in mild cases. A diagonal cross hatched strapping with adhesive plaster from close up in the crotch to the midthigh gives immediate relief in mild cases. In old recurrent cases, the author uses an elastic thigh stocking.

SURGICAL PROCEDURES ON THE BONES, JOINTS AND TENDONS

Operative Lengthening of the Femur.—Abbott and Crego²⁹ described a method of lengthening the femur in patients with unilateral shortening of the leg which they have used successfully in eight patients. The same principle was employed as in their method of lengthening the tibia and fibula previously described. After performing a Z shaped osteotomy of the shaft of the femur and inserting transfixion pins in the upper and lower ends of the bone, an apparatus is applied which permits gradual distraction of the fragments while maintaining accurate alinement. By employing this apparatus, the authors were able to obtain an average increase in length of $2\frac{1}{2}$ inches in four weeks. The lengthening finally obtained varied from $1\frac{1}{2}$ to $3\frac{1}{2}$ inches. There were no infections and no nonunions. The authors do not recommend this as a routine procedure, but advocate it in carefully selected cases.

[ED. NOTE.—Abbott and Crego's careful work and ingenious apparatus have made lengthening of the lower extremity a dependable procedure. About sixty patients have been operated on by them, with

28. Winn, D. F.: Mil. Surgeon **63**:507 (Oct.) 1928.

29. Abbott, L. C., and Crego, C. H.: South. M. J. **21**:823 (Oct.) 1928.

uniform success. There have been no disasters. At present, lengthening of the tibia and fibula is more of a standardized procedure and involves fewer difficulties than lengthening of the femur, but the latter method is still being developed.]

Results of Stabilizing Operation for Paralytic Hips.—Dickson³⁰ made a further report on the results obtained by the operative method previously described by him for stabilizing hips rendered unstable by paralysis of the gluteus maximus and minimus muscles. The operation consists in transplanting the origin of the tensor fasciae femoris from its position just external to the anterior superior spine to a new position on the crest of the ilium in the vicinity of the posterior superior spine, thus bringing the muscle posterior to the axis of the hip joint where it acts as an extensor instead of a flexor of the hip.

Dickson has operated on forty-six patients. Of these, thirty-two have been under observation a sufficiently long time to permit an estimation of the final result. In ten of these, the limp has been eliminated or greatly improved; in fourteen there has occurred a definite improvement in stability of the hip, but with a definite limp still remaining; in eight, the results have been failures in that no more improvement has been obtained than could have been expected by overcoming the hip-joint flexion deformity which was present. All the failures were in cases in which a weak or paralyzed tensor fasciae femoris muscle was used.

Operative Fusion for Tuberculosis of the Spine.—Henderson³¹ discussed the rôle of fusion operations of the spine in Pott's disease, basing his remarks on a study of 301 patients on whom this operation in one of its various forms had been performed at the Mayo Clinic between 1912 and 1925. Albee's bone graft technic was employed in 269 patients and Hibbs' osteoplastic method in 32. In a few instances after the Albee method, secondary operations were required because of fracture of the graft. Only 16 of the patients operated on were under 10 years of age, and 227 of the patients were between 20 and 40 years of age.

It was found that the length of time necessary to complete the convalescence was nearer two years than one and sometimes more, and that the patients who were able to rest and observe the general anti-tuberculous regimen improved much faster than those who did not. The author concluded that the operation has an important rôle in helping to obtain a cure and that it ought to be employed in adult patients who are in good general condition, and if there is no evidence of

31. Henderson, M. S.: Operative Fusion for Tuberculosis of Spine, J. A. M. A. **92**:45 (Jan. 5) 1929.

impending wide dissemination of the disease and no draining sinuses to contaminate the operative field. He expressed the conviction that it is useless to subject to this operation patients who in addition to Pott's disease have advanced tuberculosis of the lungs or of the genito-urinary tract.

Extra-Articular Fusion of the Tuberculous Hip in Children.—Stating his conviction that patients with tuberculosis of the hip never recover a useful degree of motion, Kidner³² advocated fusion of the hip by the extra-articular method. He considered this to be indicated even in the case of children. He has performed this operation in sixteen children and has followed them through to the end-result stage. In all cases, the progress of the disease has been arrested and symptoms relieved. He considers the juxta-articular methods of Kappis and Hibbs and the free graft method which he has devised preferable to the para-articular methods of Albee, Calvé and others. From this study he concluded that the earlier in the disease the operation is performed, the less will be the shortening and the shorter the period of invalidism.

[ED. NOTE.—We have advocated arthrodesis for tuberculosis of the hip in adults for a number of years, but have been reluctant until recently to take the same stand in respect to children and to abandon all hope of recovery without ankylosis. Subsequent experience has, however, finally convinced us that to delay operation is to expose the child to serious risks and that ankylosis in good position is not only the best guarantee of cure, but also the best means of preserving maximum function.]

Recurrent Dislocation of the Shoulders.—Oudard³³ described a new operative procedure for the relief of recurring dislocation of the shoulder which in his hands has yielded satisfactory results. Its aim was to prevent the head from leaving the glenoid by the restraining influence of a bone block. Briefly, the operation consisted in exposing the front of the shoulder by turning back the anterior border of the deltoid, splitting the coracoid process in its long axis and detaching the outer half with its muscular insertions, and dividing the subscapularis muscle and the anterior portion of the capsule. The edges of the capsule and the subscapularis muscle were then overlapped and sutured in order to reef the relaxed structures. Finally, the detached portion of the coracoid was brought up into position and its base fixed by wire to the tip of the remaining portion. This resulted in the coracoid process being prolonged a distance of about 3 cm., sufficient for it to act as a bone block preventing the humeral head from displacing anteriorly.

33. Oudard: Presse méd. **36**:201 (Feb. 15) 1928.

[ED. NOTE.—It has been reliably stated that more than 150 different operative procedures have been devised for overcoming recurrent dislocation of the shoulder. Analysis of these different operations shows that with a few exceptions they fall into three groups: first, those dealing with the capsule and employing some method of strengthening it such as reefing, overlapping, etc.; second, those dealing with the humeral head and employing some adventitious tissue to hold it in place, fixation with fascia or tendon or transplantation of muscle, and, third, those which deal with the glenoid, aiming to prevent displacement by the introduction of a bone block. All of these methods have proved effective, and the criterion for selection should be simplicity as well as reliability. Fixation of the humeral head by the use of fascia or tendon seems to have a considerable advantage in this respect.]

Tendon Transplantation Technic.—In operations for the transplantation of tendons, Royle³⁴ recommended using the transplanted tendon as a living suture. He did this by splitting off strips from the transplanted tendon, threading them on fascial suture needles and weaving them in and out of the paralyzed tendon to which the transplant is to be secured.

FRACTURES

Fractures of Metatarsals and Phalanges.—Magnuson³⁵ found from his own experience that fractures of the metacarpals and phalanges were capable of producing disability far in excess of their apparent importance because of their effect on the function of the hand. Unless the fracture is properly reduced and the fragments maintained in correct alinement, the injury results almost uniformly in stiffness of the fingers and constitutes a serious handicap.

In fractures of the metacarpal bones, it is the pull of the interossei that has to be resisted with its tendency to cause a dorsal bowing or angulation of the fragments. In fractures of the middle phalanges of the fingers, the lumbricales muscles exert an extensor action on the distal fragments while the interossei tend to flex the proximal fragment causing the forward bowing deformity which presses against the flexor tendon of the finger.

[ED. NOTE.—Fractures of the phalanges and metacarpals are serious injuries and in our experience, yield a large degree of disability. The results are bad when the fractures are not properly reduced and are far from good even when anatomic reposition is obtained. Splinting should be reduced to a minimal period and motion started as early as possible if the results are to be improved.]

35. Magnuson, Paul B.: Fractures of Metacarpals and Phalanges, J. A. M. A. 91:1339 (Nov. 3) 1928.

Compression Fractures of the Spine.—In a general survey of fractures of the spine, Osgood³⁶ found that compression fractures represent more than 50 per cent and that of these from 70 to 80 per cent involved the eleventh and twelfth dorsal or the first and second lumbar vertebrae. Most of them resulted from hyperflexion injuries. In untreated patients, one encounters the three stages of disability described by Kummell: first, the stage of initial injury; second, a period of comparative well being, and third, development of kyphos and pain. As far as diagnosis is concerned, the important thing is to suspect such an injury. Discussing the treatment in the different types of fracture, Osgood stated that fractures of the sacrum or coccyx usually respond to rest; that fractures of a single vertebra do well if the patient is treated in the recumbent position for from six to eight weeks with the aid of plaster jackets or hyperextension frames; that long standing cases, in which treatment has not been given, with persistent pain and deformity should be given the benefit of a fusion operation, which, however, should be preceded by a course of postural and corrective treatment.

Fractures of the Neck of the Femur in Childhood.—From a review of the literature, Colonna³⁷ concluded that fracture of the neck of the femur is an unusual injury in childhood. He reported six instances of this injury in children, the ages ranging from 5 to 16 years. The fractures were caused by severe violence. The symptoms were less severe than in adults, and there was only moderate disability. One of the patients was treated for a contusion of the knee for several weeks. Five of the fractures involved the cervicotrochanteric region, three being incomplete and two complete, and one was situated in the narrow portion of the neck. Five of the six patients were treated by a spica with the hip in abduction and one was treated with the hip in abduction in a Bryant frame. Three of the patients recovered with perfect function; in one, the limb was $\frac{1}{8}$ inch shorter but no limp or limitation of motion was present. One, with an incomplete cervicotrochanteric fracture, showed $1\frac{3}{4}$ inches shortening and marked limitation of motion, but was able to get about without any apparatus, and the last had $\frac{1}{4}$ inch shortening with slight limitation in abduction.

DISLOCATIONS

Apparatus for Reduction of Fracture Dislocations of the Cervical Spine.—King³⁸ described a method of reduction for fracture dislocations of the cervical spine which have proved useful in his hands.

36. Osgood, R. B.: New England J. Med. **199**:861 (Nov. 1) 1928.

37. Colonna, P. C.: Ann. Surg. **88**:902 (Nov.) 1928.

38. King, J. E. J.: Am. J. Surg. **5**:507 (Nov.) 1928.

A plaster cast was applied encircling the body, and in it was incorporated an apparatus consisting of two steel shoulder pieces mounted on which were two steel uprights terminating in a cross bar. A halter was fitted to the patient's head, and this in turn was connected with the cross bar. By means of a ratchet gear traction was exerted in the line of deformity until reduction was accomplished. This apparatus was worn for a period of six or eight weeks when a Thomas collar was applied.

Intra-Articular Dislocation of the Patella.—Jones³⁹ described an unusual injury to the patella in a boy, aged 11, following a fall. The patella was rotated 90 degrees so that the upper edge was directed backward and became wedged in the intercondylar notch of the femur. Manipulation under anesthesia failed to reduce the dislocation. At operation the knee joint was opened, and the bone forcibly levered back into position; it was then necessary only to suture the incision in the joint capsule made by the operator. The quadriceps extensor insertion had been stripped off the upper and anterior surfaces of the bone, but was not ruptured. Seven weeks after the accident, the knee joint was normal. Jones stated that fourteen similar cases have been described.

AMPUTATIONS

An Operation for Making the Forearm Prehensile after the Loss of a Hand.—Henry⁴⁰ succeeded in providing a patient whose left forearm had been amputated at the wrist with a prehensile extremity by splitting off a rod of bone from the outer side of the radius and enveloping this, together with the muscles in contact with it (flexor carpi ulnaris, flexor longus pollicis, radial wrist extensors, dorsal tendons of the thumb and the brachioradialis) and the radial artery, with skin. Active pronation of the forearm brought this newly formed digit into opposition with a fixed digit, supplied by means of a prosthesis. The patient was subsequently able to write with the left forearm. Henry expressed the belief that he could have dispensed with the prosthesis if he had partially fractured the ulna and bent it so as to give the newly formed digit a living opponent.

OSSIFICATION OF EXPERIMENTAL FRACTURES

Ossification After Fractures.—Ravdin and Morrison,⁴¹ in a series of dogs, fractured the radius by open operation and studied the rate of ossification under various experimental conditions. The animals

were divided into four groups: those in the first group were given 20 cc. of cod liver oil daily; those in the second group were given parathyroid extract Collip to raise the serum calcium level; those in the third group were subjected to thyroparathyroidectomy to lower the serum calcium level of the blood, and the animals in the fourth group were used as controls.

From their study of the results, they were inclined to minimize the effect on normal bone of a deficient inorganic phosphorus and calcium serum content. Union occurred in every instance with the exception of two hypocalcemic animals which did not live long enough for ossification to occur.

EFFECT ON THEIR FUNCTION OF STRETCHING NERVE TRUNKS

Tests on Sciatic Nerves.—By applying various amounts of tension to the sciatic nerve of a cat, Forbes⁴² demonstrated that the power of conduction of an impulse is much impaired. Even the slight amount of tension necessary to dissect out the nerve is sufficient to affect its power of conduction considerably. Tension applied to a frog's nerve, however, has much less effect than in the mammal. The mammalian nerve undergoes a recovery period after stretching; presumably a nerve with intact blood supply would recover much more rapidly.

CORRELATIONS OF INTERNAL AND EXTERNAL PANCREATIC SECRETION

I. GENERAL CONSIDERATIONS AND REVIEW OF THE LITERATURE *

G. DE TAKATS, M.D.†

CHICAGO

The relationship of the various structural elements of the pancreas has intrigued many investigators. Laguesse¹ evolved a remarkable theory of "balancement," maintaining that acini are continuously transforming into islands and that these two structures hold each other in a balance according to functional needs. A large series of experiments was conducted after the discovery of the islands to see what would happen to the islands when the external secretion was obstructed. The literature up to 1909 is summarized in Moldenhauer's inaugural dissertation;² the more recent studies have been discussed critically in Herxheimer's monograph.³ One group of investigators firmly believes in a limiting membrane and a complete independence of the islands from the rest of the pancreas. A large number of investigators claim possible transitions of acini into insular epithelium. Another small but authoritative group of investigators concedes the proliferation and transformation of duct epithelium into islands when the duct no longer excretes.⁴

A study of the development of the islands led to the uniform result that the islands originate in small buds of the duct epithelium and can be recognized as early as in the embryo⁵ of 80 mm. Here again, how-

ever, some authors deny any relationship between glandular parenchyma and islands⁶ whereas another group claims direct transitions from acini to islet tissue.⁷

The comparatively large amount of islet tissue in the fetal pancreas has been emphasized by two recent exhaustive studies of the embryology of the islands.⁸ The maximal number occurs between the twenty-sixth and the thirty-second week. The number of islands then slowly diminishes up to birth, rapidly during the first postfetal year, and then again more slowly to the fourth year, after which their number remains fairly constant.

The observations on the pancreas of congenitally syphilitic children are interesting. The great increase in interstitial connective tissue prohibits the development of the glandular element, and a large number of small ducts and islands are visible. The appearance of the pancreas of a syphilitic new-born infant corresponds to a stage seen normally around from the seventeenth to the eighteenth week.⁹

The observations in pathologic processes of the pancreas, when a gradual obstruction of the external secretion has taken place, would indicate that not infrequently hypertrophy and hyperplasia of the islands occurred. In Koch's case¹⁰ a marked increase of islands was found in spite of the fact that the entire gland had turned into an infiltrating scirrhus. That changes in sugar tolerance are frequently absent in carcinoma of the pancreas and chronic pancreatitis is generally admitted.¹¹

In experimental ligation of the duct in the fetal pancreas in pancreatic cirrhosis and in carcinoma of the head of the pancreas there is one common feature: namely, the gland does not function as a gland of external secretion. The question arises whether or not the reversion of the gland to a stage of inner secretion alone might cause a preponderance of this part of the glandular function. Mansfeld¹² pointed

out that possibly analogous conditions occur in the testis when the vas is ligated and in the parotid when Stenson's duct is tied. The thyroid gland possesses a duct at one time during development. The thyroid in the tunicates and in the amphioxus secretes a sticky material. In the higher vertebrates the internal secretion develops seemingly at the expense of the external secretion.

There is one condition that might possibly stimulate inner secretion of the pancreas, namely, the increased functional demand for such a

Division of the tail of the gland with electric cautery.

secretion. The islands do become larger in partially pancreatectomized animals,¹³ and the pancreas of the diabetic person shows adequate proof of compensatory attempts.⁹

This study was undertaken for the purpose of examining the effect of isolation of the tail of the pancreas on its insular activity. While the external secretion could flow undisturbed into the duodenum, the tail would be converted into a ductless gland. Such a procedure was

13. Allen, F. M.: *Glycosuria and Diabetes*, Boston, W. M. Leonard, 1913.

suggested by Mansfeld,¹⁴ who claimed an increase in sugar tolerance following such a procedure in the dog, lasting as long as three years. Alpern and Leites¹⁵ confirmed his results in a short preliminary report. Nather, Priesel and Wagner,¹⁶ who first confirmed Mansfeld's results, reported in a second paper that the increased tolerance is only temporary. Wohlgemuth¹⁷ found a decreased sugar tolerance following ligations of the duct and believed it to be the result of a chronic sympathicotonia with increased response to epinephrine.

This work was undertaken to study the histologic changes in the pancreas following the separation of the tail from the rest of the gland. In a second paper, the changes in sugar tolerance will be discussed, while other papers will deal with associated effects produced by partial pancreatic obstruction.

CORRELATIONS OF INTERNAL AND EXTERNAL PANCREATIC SECRETION

II. THE HISTOLOGIC CHANGES IN THE ISOLATED TAIL OF THE PANCREAS *

G. DE TAKATS, M.D.†

CHICAGO

The purpose in this study was to examine the three main structural elements of the pancreas—acini, ducts and islands—after a part of this gland had been excluded from external secretion. It must be emphasized that this procedure is not identical with ligation of the duct, which method has been used to a great extent experimentally.¹ The exclusion of pancreatic juice from the intestines results in serious nutritional disturbances and may influence the inner secretion of the pancreas. Ligation of the tail of the pancreas, as suggested by Mansfeld,² leaves a sufficient part of the gland to secrete ferments and turns only ductless that part of the gland which is known to contain comparatively more islet tissue.

Recent studies by Ukai,³ Herxheimer and Carpenter⁴ and Jorns⁵ uniformly state that a sclerosis of the pancreas takes place following ligation of the duct. The islands, however, resist this process, and may even increase in size. They even survive transplantation⁶ for a long time. Special stains have been employed by some workers to identify the remaining structures as islet tissue.⁷ A systematic examination of

the separated tail at various intervals to study the degenerative and regenerative processes of the pancreas was undertaken to serve as a basis for further studies.

METHOD OF EXPERIMENTATION

Healthy dogs weighing from 10 to 15 Kg. were used. The operation was performed with the animals under ether anesthesia after a preliminary injection of morphine, $\frac{1}{4}$ grain (16 mg.), and atropine, $\frac{1}{60}$ grain (1 mg.). Through a small midline incision the index finger of the left hand palpated the pylorus and delivered the mobile duodenum into the wound. This brought the pancreas into the field. At the point where the tail of the pancreas borders the fixed part of the gland, a massive ligature was thrown around the gland. In later experiments the gland was cut between the two ligatures, or simply cut and the individual bleeders tied. In the last six cases the gland was cut with the electric cautery.* This made the use of a ligature unnecessary. The absence of foreign material, thereby lessening the tissue reaction around the ligatures, was thought to be of some importance.

Sections were taken for histologic study at various intervals from the isolated and undisturbed portion of the gland. Ten of the twenty-five dogs used in this series lived a year or longer, whereas eighteen could be observed for at least six months. They were on the standard diet, and lost weight during the first few weeks, but maintained their weight later and seemed in good condition. Occasional blood counts revealed no kennel anemia. The removed specimens were fixed in a diluted solution of formaldehyde, U. S. P. (10:1) and stained with hematoxylin and eosin. Later, the neutral formol-Zenker fixation was used, and Bensley's special stains were employed.

SUMMARY OF HISTOLOGIC OBSERVATIONS

Two days following separation of the tail, the dominating impression was that of edema. The tail was soft and friable and was markedly swollen. The small ducts were dilated, and the acini were markedly distended with stagnant secretion. Their epithelium was flattened. The nuclei did not stain well, were irregular and had a hazy contour. The islands seemed swollen, but generally were intact (three specimens).

Two weeks following separation of the tail, the tail looked anemic and grayish white. Its consistency was hard and nodular, similar to that found in chronic pancreatitis of man. Under the microscope, the individual lobules were compressed and separated from each other by a moderate increase of connective tissue. This concentric, intralobular fibrosis caused the remaining parenchyma to stand out clearly. The acini still maintained their form, but the individual cells had partly undergone degeneration. The protoplasm consisted of numerous vacuoles; the nucleus was fragmented and pyknotic. The zymogen granules stained poorly. The small ducts were dilated; their epithelium showed infolding

8. Prof. W. T. Bovie and his staff of the department of biophysics have given their utmost cooperation. Dr. Bovie's newest model of high frequency apparatus was used (Surg. Gynec. Obst. 47:751, 1928).

at certain places. There was marked mitotic activity. The islands seemed well preserved and showed no evidence of degeneration. In the sclerotic gland with compressed acini, they stood out clearly. There was no evidence of any activity on their part (three specimens) (fig. 2).

Four weeks following separation of the tail, the tail was even more sclerotic. It had turned into a whitish, narrow cord. Its consistency was hard and granular. There was more connective tissue than in the previous specimen, and not only interlobular but intralobular strands of fibrous tissue were seen. An increase in fatty tissue could also be observed. The acini were hardly recognizable, except as irregular masses

Fig. 1.—Two weeks following ligation of the tail. There is a moderate amount of perilobular sclerosis. The edema is most marked in the connective septums, but the islands are also swollen; low power.

of detritus into which connective tissue proliferated. The ducts were not dilated markedly; their wall was thick. Mitotic activity and occasional buds and infolding of the epithelium could be observed frequently. The islands did not seem increased in size or number. They stained well, but showed a certain diffuse hyaline-like structure in their center. There was no mitotic activity (two specimens) (fig. 2).

Six weeks following the separation, the tail was completely cirrhotic. Under the microscope, a dense connective tissue had taken the place of the lobules. Acinar structures could not be recognized. There was a marked proliferation of the minute ducts, which spread lengthwise and

crosswise over the field. Their epithelium was in a stage of mitotic activity. Occasionally, small buds, papillary folds and cystic dilatations could be found. The islands were still preserved, but were not particularly large or numerous except in one specimen, in which they stood out in large numbers. They did not show mitotic activity (three specimens) (figs. 3 and 4).

After twelve weeks, the microscopic appearance of the ligated tail was that of a whitish-gray firm cord. Histologically, the lobules had been compressed to small irregular structures. The connective tissue had proliferated into these lobules. The larger ducts were dilated, but

Fig. 2.—Four weeks following ligation. There is a marked increase of connective tissue, not only around but in the lobules. The acini are shrunk, and their cell nuclei are pyknotic. The islands are well preserved and fairly numerous; low power.

a few minute ducts were visible. The islands were numerous, and were not only well preserved, but larger in diameter. They showed mitotic activity. On one slide, in which the tail had been separated by the high frequency current, there was much less fibrosis, and the acinar structure was well preserved. The islands were numerous on the slide, and the number of capillaries around the islands was striking. This whole slide was characterized by a lack of fibrosis, but a large number of dilated capillaries was seen. The epithelium of the ducts was columnar with frequent mitoses and infolding. There was a mass of desquamated epithelium in the lumen (figs. 5 and 6).

Fig 3—Isolated tail of the pancreas, six weeks following division with the cautery. The black areas represent glandular parenchyma staining red with acid fuchsin-methyl green stain. The fibrosis is fairly marked in the upper half of the section. The main duct is seen markedly dilated.

Fig 4—Same section as in figure 3, under high power. The lobuli are shrunken, and there is a great amount of connective tissue between the lobules. The islands are well preserved and are not involved in the sclerotic process.

Fig. 5.—Twelve weeks following the isolation of the tail. There is a diffuse sclerosis of the gland. There are numerous small and minute ducts embedded in the sclerotic tissue. The epithelium of the ducts is high and shows infolding.

Fig. 6.—Same section as in figure 5, under high magnification, showing a well preserved island of considerable size. Below it is connected with another island which is probably the same island but hardly connected at the level of the section.

After sixteen weeks, the diffuse sclerosis with small remnants of acini dominated the field. The vessels had thick walls but were patent. The small ducts were numerous, and a large number of minute ducts was visible. Large masses of accumulated cells stood out in the connective tissue. Some of them were miliary abscesses. Others showed conglomerations of histiocytes and macrophages. There were epithelial cells with large light protoplasm which had the usual appearance of islet tissue. They were identified as such with special stains. These islets had a diameter of from three to thirty times the normal. In many

Fig. 7.—Sixteen weeks following ligation of the tail; there is complete absence of acini, and thickened but patent vessels. An intact ganglion is shown, and a large island appears in the left upper quadrant of the picture. There is no fibrosis within the island.

instances, they were grouped around a small duct with thickened walls (fig. 7).

After twenty-four weeks, no acinar elements could be detected in the sclerotic mass. Islet tissue was well preserved with typical capillary arrangement. The connective tissue was arranged in a wavy, circular configuration around the islands. In some places the solid epithelial masses seemed to be broken up by fibroblasts, and individual cells were visible. These nuclei seemed shrunk, and pyknotic (figs. 8 and 9). A transplant of a portion ligated twelve months previously had been made into the omentum. In the omental fat a large number of ducts

Fig. 8—Twenty-four weeks following ligation; there are a number of small newly regenerated ducts, similar to the regeneration of bile ducts in cirrhosis of the liver. There are remnants of lobules seen in the periphery of the picture. There are small areas of round cell infiltrations, plasma cells and histiocytes as a result of minute focal necroses.

Fig. 9.—Twenty-four weeks following ligation. A large island, completely surrounded by insular waves of connective tissue, is seen. The island seems well preserved; the nuclei stain well.

with thick walls and high and frequently infolding epithelium were seen. Large structures of dendritic design, with light protoplasm and sharply staining nuclei were the only other cellular elements in the slides. These solid strands sometimes were drawn out to narrow cords. In other places, they formed round or oval structures with a lumen in the middle, as if they originated in ducts. Occasionally a small duct was found in the middle of these islands, with infolding epithelium. The transplant was well vascularized, a number of thick vessels surrounding the cellular elements in the omental fat. The sympathetic ganglions

Summary of Histologic Observations Following Isolation of the Tail of the Pancreas, with Four Additional Transplants into the Omentum

Postoperative Period, Days	Number of Specimens	Acini	Ducts	Islets	Ganglions	Connective Tissue
2	3	Distended	Dilated	Edematous	Edematous	General edema
14	3	Preserved	Epithelium active	Well pre- served	Well pre- served	Perilobular fibrosis
23	2	Poorly staining	Walls thick; infolding epithelium	Well pre- served	Well pre- served	Perilobular and intralob- ular fibrosis
42	3	Detritus	Desquam- ating epithelium	Numerous mitoses; well preserved	Well pre- served	Dense fibrosis
84	3	No acinar structure	Dilated; few minute ducts	Numerous; large diameters	Well pre- served	Very little fibrosis in the cauter- ized specimen
112	2	No acini plasma cells; histiocytes	Numerous minute ducts; buds	Large; mitoses	Well pre- served	Very dense fibrosis
168	2	No acini	Ducts less numerous	Partly in- vaded by fibrosis	Well pre- served	Intense sclerosis
210	2	No acini; fat	Occasional ducts	Well pre- served	Well pre- served	Intense sclerosis
330	1	Fat	Occasional ducts	Well pre- served; vascular	Well pre- served	Intense sclerosis
300 days; 160 days in omentum	4	Fat	Small ducts	Numerous	Well pre- served	Intense sclerosis

were also well preserved. The number of ducts was markedly decreased in contrast with slides from transplants of less duration. When they were seen, their epithelium was active, showed a number of mitoses and was cuboid or cylindric (figs. 10 and 11).

Five such transplants remained in the omentum for six months or more. They all showed the same picture. The longest time was 450 days, the shortest, 150. Briefly, they were all characterized by a complete absence of zymogenic cells and by a dense fibrous tissue, in which only two elements survived—small ducts and solid masses of large cells—which stained like islets. The capillary arrangement around such masses was also similar, if not identical, to that around the normal islets. The diameter of these solid cell complexes was from ten to thirty times that of the islets in the dog. Other cell complexes of mesoblastic origin, as described in previous slides, were also encountered (see table).

Fig. 10.—Ligated tail of the pancreas grafted into omentum. The tail was separated one year before; it had been grafted in the omentum for three months. There is evidence of a good blood supply; a firm sclerotic mass was embedded in omental fat.

Fig. 11.—Same section as in figure 10, under high magnification. There are solid cell complexes surrounded by connective tissue, which may be identified with special stains as islands. Other groups of cells are seen, which consist of histiocytes and plasma cells, indicating the reaction of the omentum to the graft. No acini or ducts are seen.

OTHER OBSERVATIONS RELATING TO THE OPERATIVE PROCEDURE

The separation of the tail was first accomplished by throwing a wide tape around the body of the pancreas; also heavy linen ligatures and strips from the anterior rectus sheaths were used. When the abdomen was reopened at frequent intervals for obtaining histologic specimens, it was found that these ligatures would cause a marked inflammatory reaction with the outpouring of an exudate which in later laparotomies had organized into dense adhesions. In operations, when a ligature had been thrown around both head and tail for other purposes,⁹ the right lobe of the liver was invariably sealed down to the duodenum and could be separated only with some difficulty. There was no evidence of fat necrosis, for which careful search was made. Fat necrosis, however, was encountered when extensive charring of the pancreas was produced with the electric cautery.

It was also found that in spite of the marked fibrosis and foreign body reaction that occurred around such ligatures a reestablishment of continuity between the body and tail was not impossible, as in two dogs the acinar structures were well preserved and the ducts undilated three months after the operation.¹⁰ After this experience, the pancreas was doubly ligated and cut between two ligatures. The edema and exudation were just as marked as before, but I never encountered necrosis of the pancreas. As a matter of fact, it has been shown¹¹ that the pancreas may be simply severed and after ligation of the bleeding points be permitted to drain into the abdominal cavity without the appearance of necrosis in the pancreas.

The next modification was the use of Dr. Bovie's electric cautery. There was no need of ligatures either of the body or of the tail, and bleeders did not have to be tied. There was, however, a thin layer of desiccated tissue on either side of the cautery incision. At relaparotomy six weeks later, I found that the body and tail had been drawn together, and the original cautery incision could not be recognized without difficulty. This led me to interpose omentum between the two separated surfaces. This piece of omentum, which was wrapped around the separated tail, was examined histologically in six instances with regard to fat necrosis. In no case was it found.

The separation of the tail with the cautery, followed by wrapping it with omentum, was the technic finally adopted. In order to find out if the well vascularized omentum around the tail would hasten the absorption of cellular elements, free transplants of such tails that had been separated six months previously were made into the omentum and left

9. De Takats, G., and Nathanson, I. T.: The Effect of Ligation of the Tail of the Pancreas on Blood Diastase, *Arch. Surg.*, this issue, p. 788.

10 The reestablishment of continuity is not undesirable, as it seems to lessen the degree of sclerosis. This question will be discussed in a later communication.

11. Crandall, L. A.: Personal communication to the author.

for three months. A section of such a transplant showed enormous islands with mitoses, all signs of sufficient circulation without any evidence that these structures were being absorbed. Ukai³ saw islet tissue transplanted into the spleen after 450 days.

COMMENT

From the histologic studies it would appear that the separation of the tail of the pancreas from the rest of the gland results in a gradual disappearance of the acinar structures, replaced by fibrosis. There is no sudden necrosis "en masse" as would occur if the circulation was obstructed. It is possible, however, that circumscribed necrotic areas may result from acute or chronic pancreatic retention, as emphasized by Balo and Ballon.¹² The obstruction to the excretion of pancreatic juice must result in a greater intraductal pressure than the secretory pressure can overcome. The studies of Bensley¹³ have particularly emphasized that duct epithelium soon starts to proliferate, becomes columnar and shows infolding. I have found this in my slides. The islands do not show any change at first aside from an initial edema, but from the sixth week on there is evidence of proliferation in the islet cells, and more new islands are seen. Whether these islands originate in the persisting islands, from scattered islet cells in acini, from acinar cells or from the proliferating duct cells, is not my purpose to study. All I can state is that I am confronted with large cell complexes, which show the vascular arrangements and staining properties of islet tissue. Such cell groups do not seem to degenerate, even if transplanted into omentum. The intensity of sclerosis is probably variable in different species; it is much less marked in the guinea-pig or in the rabbit.¹⁴ A histologic study cannot give any information as to whether these cell complexes are functionally identical with islet tissue or whether their nervous control and physiologic response to stimuli are the same. Further work is necessary to study this question.

SUMMARY

1. The splenic portion of the pancreas was isolated from the rest of the gland in twenty-five dogs. The division with an electric cautery followed by wrapping omentum around the tail seemed the most satisfactory procedure.

2. Specimens were taken from the isolated tail at intervals of from two days to one year. After a short period of edema, a gradual destruction of the acinar elements takes place. There is an increasing amount

13. Bensley, R. R.: Studies on the Pancreas of the Guinea Pig, *Am. J. Anat.* **12**:297, 1911.

14. Bensley, R. R.: Personal communication to the author.

of connective tissue, first around and then within the lobules, and this finally results in pancreatic cirrhosis. The ducts are first dilated, then show proliferation and infolding of their epithelium; occasionally buds of epithelium form, resembling an early stage of embryonic development. A number of minute ducts also appear. The islands show edema for the first two weeks. Later there appear large solid cell complexes showing the vascular arrangement and staining properties of islet tissue. Fibroblasts may invade and break up the islets as the cirrhosis progresses.

3. Such an isolated tail does not tend to degenerate and undergo absorption for at least three months, if a free transplant of it is made into the omentum.

CORRELATIONS OF INTERNAL AND EXTERNAL PANCREATIC SECRETION

III. THE EFFECT OF LIGATION OF THE TAIL OF THE PANCREAS ON DIASTASE IN THE BLOOD *

G. DE TAKATS, M.D.†

AND

I. T. NATHANSON, B.S.

CHICAGO

In previous communications,¹ I have described the histologic effects produced by separating the tail of the pancreas from the rest of the body. It has been known since the work of Wohlgemuth,² confirmed by Noguchi³ and by Gould and Carlson,⁴ that the diastase in the blood rises for a short time following ligation of the duct. Our histologic studies have shown the presence of marked edema of the separated tail for the first two weeks, later followed by a gradual atrophy of the glands of external secretion. In this series of experiments we have attempted to correlate our morphologic observations with values for diastase in the blood.

The purpose of this study was to establish with a simple test whether ligation of the tail would cause an increased absorption of pancreatic diastase. It was undertaken to establish the duration of the pancreatitis following ligation of the tail. As clinical experience has repeatedly shown, acute pancreatitis will cause a marked rise in diastase in the blood. In ninety-seven cases of acute necrosis of the pancreas collected by Schmieden and Sebening,⁵ seventy-eight cases (80 per cent) showed abnormally high figures. At the fifty-first German Surgical Congress,⁶

Guleke, Unger and Heuss and von Redwitz emphasized the value of determinations for diastase in the blood or the urine. While it is recognized that determinations for lipase in the blood are a more sensitive index of pancreatic absorption,⁷ the simplicity and ease with which diastase can be determined in the blood made this test preferable. It can be carried out in about forty minutes and is therefore useful in emergencies.

METHODS OF EXPERIMENTATION

Normal healthy dogs were used in the first control series. After the injection of morphine, $\frac{1}{2}$ grain (0.02 Gm.), and atropine, $\frac{1}{60}$ grain (0.001 Gm.), ether anesthesia was induced. The abdomen was opened with a short midline incision starting just below the xyphoid process. The duodenum was pulled forward two or three times. In other words, all the factors that are present outside of pancreatic ligation and that might have influenced our values were introduced. The duodenum was then replaced in the abdominal cavity. In a series of five dogs the values for diastase were taken every second day before, and a week after, the operation.

Determinations for diastase were made according to the original method of Wohlgemuth, as described by Unger and Heuss.⁸ For the test the following materials were necessary:

2 cc. of blood serum (or urine)	2 pipets
1 per cent solution of sodium chloride	10 test tubes
1 per cent soluble starch	
Fiftieth-normal iodine solution	

About 10 cc. of blood is taken from the vein in a centrifuge tube, allowed to clot and separation of the serum permitted. One cubic centimeter of serum is pipetted into the first and second tubes. One cubic centimeter of 1 per cent solution of sodium chloride is pipetted into every tube. After the proper mixing of the serum and sodium chloride in tube 2, 1 cc. is again pipetted into tube 3. Here again after the proper mixing 1 cc. is pipetted over to tube 4, and so on up to the tenth tube, when the last cubic centimeter pipetted out of the tenth tube is discarded. To every tube 2 cc. of the soluble starch solution is then added, well mixed, and the whole system of tubes incubated in a thermostat at 38 C. for thirty minutes. At the end of that time, the fermentation is abruptly stopped by immersion of the tubes in cold water for a few minutes. Three drops of fiftieth-normal iodine solution are added to each tube. The undigested amylo-dextrin gives a blue reaction, the erythro-dextrin, red and the achro-dextrin, yellow. The end-point is read at the tube which shows the first trace of purple without being a solid blue. The quantity of ferment is calculated by raising the amount of starch (2 cc.) to the power which is indicated by the number of that test tube which is the last not to turn blue. For instance, if the end-point is at the fourth tube, $D = 2^4 = 16 \frac{38^\circ}{30}$, indicating at the same time the temperature and duration of incubation. The Wohlgemuth unit, then, is the amount of diastase which will digest 1 cc. of 0.1 per cent of starch solution in thirty minutes at a temperature of

8. Unger, E., and Heuss, H.: Zur Frühdiagnose der akuten Pankreasnekrose, Zentralbl. f. Chir. **53**:1500, 1926.

38 C. The diastatic values in the blood of the dog, $D = \frac{38}{24h}$, vary between 160 and 320.² Our normal figures taken in more than fifty individual determinations vary between 32 and 64, with an occasional reading of 96 following an incubation period of thirty minutes.

Following the exploratory laparotomy, determinations for diastase were made on the second, fourth, sixth, eighth and tenth days. We found that food, at least the food which the dogs are fed in the laboratory, does not influence values for diastase. Blood did not have to be taken then on the fasting animal.

In a second series of experiments, the tail of the pancreas was ligated as described in a previous communication,⁹ and determinations for diastase were made every second day for two weeks.

In a third series of experiments, not only the tail but the head of the pancreas was ligated with a double silk ligature. Thus, only about the size of a quarter

Chart 1.—Diastatic values in the blood following an exploratory laparotomy with the animal under ether anesthesia, with the preliminary medication of morphine and atropine. The duodenum was pulled forward and the pancreas lightly grasped. The maximum rise is 128, average rise, 96. Numbers 1, 2, 3, 4 and 5 indicate the five dogs used in this control series.

Chart 2.—Diastatic values in the blood following ligation of the tail of the pancreas. There is a small initial rise, comparable to that of the first chart in dogs used as controls, but more protracted, and a sharp secondary rise between the sixth and eighth days. The peak in this series is reached on the tenth day, after which there is a sharp drop.

remained around the main duct for the purposes of external secretion, while the rest of the gland was barred from secreting into the duodenum. Thus, a maximum amount of ferment absorption could be expected without the elimination entirely of the secretion into the duodenum.

RESULTS

Following an exploratory laparotomy with the animals under ether anesthesia, with preliminary medication of morphine and atropine, there

9. De Takats (footnote 1, second reference).

was no appreciable rise in diastase in the blood. The maximum rise on the second day was $D \frac{38}{30} = 128$, the average rise, 96 (chart 1). The ligation or isolation of the tail of the pancreas resulted in a small but definite initial rise, followed by a second marked rise beginning between the sixth and eighth days. The diastase in the blood rose to 1,024 and 1,536 (chart 2). In a third series, in which both the head and the tail were ligated, sharp immediate rises were observed up to 3,072. About the tenth day, the values came down to normal and remained so (chart 3).

Chart 4 shows the average values of the three series of experiments on a total of fifteen dogs.

Chart 3.—Diastatic values in the blood following ligation of both head and tail of the pancreas. There is a sharp early rise, and a sudden drop on the tenth to twelfth days, after which the diastase does not rise.

COMMENT

Values for diastase in the blood of the normal dog seemed fairly constant and varied from 32 to 64 with the technic described. Food or an exploratory laparotomy did not influence these values to any extent. The ligation of the tail of the pancreas resulted in a small initial rise followed by a large secondary rise in the diastase in the blood. Such a secondary rise was described after ligation of the pancreatic duct by Gould and Carlson. They expressed the belief that the second rise occurred when the zymogenic cells recuperated from the edema which followed the operation. In our histologic studies, edema was the dominating picture observed immediately following ligation. As it subsides around the tenth day following operation, the coincidence of such histologic observations with the rise in diastase in the blood is striking. The amount of gland tied off at the operation seems to influence the diastatic values. In the third series, in which both the head and the tail

were ligated, the diastase rose to enormous values soon after operation. No secondary rise was noted, however, as if by that time there was no further excretion of diastase. At all events, this determination seems to be a sensitive index of acute pancreatic obstruction. That it gives only increased values in acute conditions has often been emphasized clinically. This is easily understood if we consider that the acini, the excreting ducts of which are obstructed, undergo degeneration as reported in our histologic study. The fact that the high diastasic values following glandular ligation return to normal within two weeks might be interpreted in a way that acinar elements in the ligated portion have ceased to excrete. This question is now under investigation with another method of approach. The formation of a pancreatic fistula from the

Chart 4.—Average curves of charts 1, 2 and 3. The small early rise following ligation of the tail is more protracted than in the control animals. The secondary rise in dogs with ligation of the tail shows its peak when the enormous rise following ligation of the head and tail has almost subsided (tenth day). *A* shows the average curve for the dogs used as controls; *B*, that for dogs on which ligation of the tail was done, and *C*, that for dogs on which ligation of both the head and the tail was done.

isolated tail is not probable, if the obstruction can be maintained for two weeks.

The original test of Wohlgemuth is simple and rapid and can be carried out without any special apparatus. We were especially interested in using such a test because of the possibility of a wider clinical use. We are aware that this method has been modified repeatedly and other methods described. Some insist on the use of buffer solutions in order to establish an optimal p_H for diastasic activity. A recent article of Elman and McCaughan¹⁰ measured the lowering of the viscosity as

10. Elman, R., and McCaughan, J. M.: The Quantitative Determination of Blood Amylase with the Viscosimeter, *Arch. Int. Med.* 40:58 (July) 1927.

effected by the starch-splitting ferment. While the importance of the buffers is clear in determinations of diastase in feces and urine, the buffer system of the blood is a reasonable safeguard that large variations in p_H will not occur. While the optimal p_H may not be thus obtained, the figures are comparable. The use of buffer solutions complicates the method without being of marked advantage. A few comparative determinations with the buffer method of Stafford and Addis¹¹ convinced us that buffering in the blood is not of any advantage. Our curves showing the amount of diastase following ligation of the tail or the head and tail show that a definite and constant rise is estimable.

We have no experience with the interesting method of Elman and McCaughan, as our work was completed at the publication of their method. These authors made the statement that diastase in plasma deteriorates rapidly, whereas diastase in serum retains its potency. We have used diastase in serum all through our work and have kept serums in the icebox for two days without deterioration. Checks on the p_H of serum have shown no change in the serums which would warrant buffering.

Another advantage of determining diastase in the blood instead of in the urine is the factor of concentration and the rate of excretion of urine, as has been emphasized by Stafford and Addis. Determinations of diastase with feces introduce additional difficulties, as recently discussed by Wolfer and Christian.¹² The clinical application of a simple determination of diastase in the blood in suspected pancreatic injuries and in acute necrosis of the pancreas is well worth considering. No increase can be expected in chronic pancreatitis and obstruction.

SUMMARY

1. Isolation or ligation of the tail of the pancreas leads to an early increase in diastase in the blood, followed by a secondary rise about the seventh day. From our previous histologic studies, we believe that the secondary rise may be due to the disappearance of the initial edema.
2. The rise in diastase seems to be proportionate to the amount of tissue ligated. The ligation of both the head and the tail of the pancreas gave much higher rises in diastase than ligation of the tail alone.
3. The return of the diastasic values to normal at the end of two weeks would indicate that external secretion is not to be expected or feared from the ligated portion after two weeks.

EXPERIMENTAL SARCOMA OF BONE*

CHARLES L. CONNOR, M.D.

SAN FRANCISCO

It is known that an experimental tumor on transplantation invariably reproduces the same kind of tumor as to cell type. For instance, the Rous sarcoma always produces a fibrosarcoma whether it is injected into muscle, bone, connective tissue or an internal organ, such as the liver. When, therefore, an opportunity came to work with an endothelioma, I seized the chance to observe its behavior when injected into the bone-marrow of chickens. The purpose of such a procedure was several fold. First, it was desired to see to what extent it might produce a tumor resembling the much disputed tumor described by Ewing as an endothelioma of bone. Second, it seemed important to watch the development of tumor of the bone-marrow from its inception, a thing impossible to do in man, since in the latter it usually has advanced considerably before it is discovered. Third, the reaction of the bone itself to the presence of cells of known origin might throw some light on the type of cell that is capable of forming bone.

This tumor was found by J. A. Murray, director of the Imperial Cancer Research Fund, London, in a Rhode Island Red chicken. It was furnished me through the courtesy of Dr. W. E. Gye. The material received had been dried in London three weeks before it was used. It was said by Murray that filtrates of the tumor, as well as suspensions of the cells, would reproduce the tumor on injection into an homologous strain of chickens. The new tumors therefore presumably arise from cells of the new hosts, and not from the transplants.

Murray, in a communication through Dr. Gye, said that by serial sections he had observed the tumor arising from the lining cells of blood vessels. My first experiment was an attempt to prove this. Suspensions of the tumor cells were injected into the thigh muscles of chicks, and the animals were killed at various intervals in order to watch the development of the resulting tumors. Into half the chicks, a small amount of ground carbon was injected with the tumor cells in order that the sites of the inoculated material might be localized. The tumors grew, as a rule, rapidly. Within thirty-six hours, microscopic nodules were present between the muscles. When carbon also was present, growth was even

* Submitted for publication, March 22, 1929.

* Part of this work was done in the Department of Pathology, Harvard Medical School. The x-ray pictures were made at the Peter Bent Brigham Hospital, Boston, under the direction of Dr. M. S. Sosman.

more rapid. Carbon alone, injected into several control chicks, or into the opposite thighs of the chicks receiving tumor cells, caused a proliferation of the same kind of cells as those which formed the tumor. This proliferation never became malignant, but remained as a typical foreign body reaction. Both the tumor cells and the cells responding to the injection of carbon alone were phagocytic. Many of them became filled with the carbon (fig. 3).

Because of the rapidity of growth and the intimate intermingling of tumor cells, blood vessels and connective tissue, it was not possible to say,

Fig. 1.—An early stage of the tumor, starting in the muscles of the thigh. The cells appear to be growing from the sarcolemma, and are forming sinuses; $\times 80$.

beyond the shadow of a doubt, from which cells the tumors arose. In muscle, the first cells to appear seemed to come from resting cells between the muscle or the connective tissue fibers, or perhaps from the mesothelium forming the surface cells of the sarcolemma. These cells were undifferentiated and contained considerable lightly staining cytoplasm and round or oval nuclei with prominent nucleoli. They resembled the reticular cells of man more closely than the endothelial type of cells. The former have a reticulated chromatin, the threads of which commonly join at a concentrically placed nucleolus; in the latter, the chromatin is

in finely scattered granules, among which nucleoli can often not be distinguished. The cells of the tumor in the chicken thus resembled the cells lining lymph sinuses, and were comparable to the Dorothy Reed cells of the Hodgkin's type of lymphosarcoma. They formed spaces and lined them (fig. 1), and some of the spaces contained blood. Mostly, however, the tumor grew in lobulated masses, and had a capillary stroma, except where thin bands of fibrous tissue divided up the tissue.

In bone-marrow, the tumor cells appeared to arise from the indifferent cells lining the marrow sinuses, and appeared first as spindle cells without fibrillae. Here, again, it was impossible to say from which type

Fig. 2.—A proliferation of cells in the bone-marrow four days after the injection. Carbon is present. There was no evidence of tumor in the x-ray picture; $\times 80$.

of cells the tumor cells arose. There seemed to be a general reticular hyperplasia, and the cell which became a tumor cell could not be distinguished from a similar (or identical) cell which formed the blood cells. Carbon pigment stimulated the proliferation of the same kind of cell here also.

In transplantations of the tumor cells into the bone-marrow, young chicks from 3 to 10 weeks old were used. It was comparatively easy to inject the ground-up tumor suspended in salt solution into the marrow cavity of the tibia through the proximal articular surface. The animals were killed from time to time, some as early as twenty-four hours after the inoculation. X-ray pictures were made from the first day, until it

was found that tumors could not be demonstrated before about the fourteenth day. Sixty-five chickens were used, and practically all developed tumors. The results, in those which were allowed to run the full course, were about the same. Therefore, to be brief, only a few cases will be given in detail.

At twenty-four hours, no tumor could be observed microscopically. Tumor cells which had been injected could be identified in some cases, and these were undergoing autolysis. On the second and third days following the injection, a reaction on the part of the marrow could be observed as a proliferation of undifferentiated cells. These cells appeared

Fig. 3.—A higher magnification of the cells four days after the inoculation with the tumor. Their phagocytic character is shown; $\times 480$.

no different from those which presumably were forming white blood cells, and at this time a definite diagnosis of tumor could not be made. In those cases in which carbon had been injected, the cells were phagocytosing the pigment. Definite tumor could be diagnosed on the fourth day in four chicks by microscopic examination (fig. 4). The cells at this stage were of spindle shape, but staining with phosphotungstic acid hematoxylin failed to demonstrate fibrogia.

At later stages, the tumor grew up and down the medullary cavity, though in most cases the tumor reached the outside before entirely replacing the bone-marrow. Tumor could not be demonstrated by palpation or by the x-rays in any chick before the fourteenth day. Of ten

chicks that were allowed to live beyond this period, one contained a palpable tumor on the fourteenth day, three on the fifteenth, two on the sixteenth and two on the eighteenth. The x-rays revealed tumors in one chick on the fourteenth day, in two on the fifteenth and in one on the sixteenth. These were animals which had been followed systematically by taking daily pictures. Two such chicks died before palpable tumors appeared, one on the fifteenth day and one on the nineteenth day. Each of these contained metastases in the liver and the spleen, and gross tumor was present in the tibia (on longitudinal sectioning),

Fig. 4.—The picture shows the size of the tumor of the bone-marrow at four days. No carbon was injected. No tumor was shown by the x-rays; $\times 80$.

but tumor could not be diagnosed from postmortem x-ray pictures. All the chicks that were allowed to die of tumor succumbed before the twenty-second day following the injection. The clinical course of one chicken is given as an example of the usual progress of the tumor.

Chicken 36.—A suspension of cells from a large tumor of the thigh was injected into the left tibia of chick 36 when it was about 2 months old. X-ray pictures were made daily, beginning on the sixth day, until the death of the chicken, on the eighteenth day. The tumor became visible on the sixteenth day (fig. 5 A); a slight roughening of the periosteum was shown, with a suggestion of fine, radiating lines. On the seventeenth day (fig. 5 B), both sides of the shaft showed rarefaction and had a mottled, ragged appearance, and radiating lines

and an elevated periosteum were present on one side. Fig. 5 *C* shows the tumor on the eighteenth day, when a definite fusiform thickening of about a third of the shaft could be detected.

At autopsy, huge metastases were found in the liver and metastases also in the lungs and the spleen. The tibia contained tumor throughout the marrow cavity, and this had broken through in the region of the nutrient artery to form a subperiosteal mass which completely encircled the cortex. Between the periosteum and the cortex there was a new formation of bone. In the medullary portion, the tumor was soft and gray and contained numerous small areas of necrosis (figs. 6 and 7 show a more advanced tumor of similar appearance). Histologically, the tumor consisted of the type cells, previously described, in a capillary stroma. These cells seemed to be differentiating into the cells that were forming bone beneath the periosteum.

Fig. 5 (chick 36).—*A*, the first definite evidence of tumor shown by the x-rays, on the sixteenth day; *B*, the tumor on the seventeenth day, showing rapid growth; *C*, the tumor on the eighteenth day, on which the chicken died. The x-ray picture is of the detached leg.

A single experiment was undertaken with the Rous fibrosarcoma for purposes of comparison with the endothelial tumor. A cell suspension received from Dr. J. H. Mueller of the Department of Bacteriology, Harvard Medical School, was injected into two barred Plymouth Rock chickens. The site of injection was, as in the case of the endothelial tumor, the tibia. One animal was killed on the sixteenth day. A definite tumor was present, which was passing out into the subperiosteal space around the nutrient artery (fig. 8). The second chicken was killed on the twenty-first day. A fusiform tumor was found similar to

that formed by the endothelioma. The cells of the tumor were apparently forming the bone that was present in considerable amount between the periosteum and the cortex.

The endothelial tumor was not an exact reproduction of the endothelial myeloma of Ewing. It had characters both of Ewing's tumor

Fig. 6.—A tumor that caused death in twenty-one days with generalized metastases. The medulla is filled with tumor, the cortex is eroded and masses of tumor and new bone are present between the periosteum and the cortex; $\times 4$.

and of osteogenic sarcoma. The type cell, as has been said, was different, though the cells of chickens do, in general, differ from the cells of man in several respects. The tumor grossly resembled Ewing's tumor in that it fairly well filled the marrow cavity, it occupied more than a third, sometimes nearly all, of the shaft, and it had osteolytic rather

Fig 7.—The tumor forms bone only when confined beneath the periosteum. At one place in this section, where the periosteum has broken down, no bone is formed, $\times 4$ Figure 11 shows the x-ray picture of this bone

than sclerosing properties while confined to the medulla and the cortex. It was pointed out previously¹ that any tumor of bone (metastatic or primary) may cause the formation of radiating spicules as seen by the x-rays. This, however, is much more common in osteogenic sarcoma than in other tumors, and is one of the least conspicuous features in Ewing's tumor. The method of growth of this experimental tumor beneath the periosteum exactly duplicated a subperiosteal osteogenic sarcoma as seen in man. Such tumors were previously called periosteal sarcomas, until Codman² pointed out that all of them are both medullary and subperiosteal, and claimed that all arose in the medulla. The

Fig. 8.—Rous sarcoma. This shows one way by which the tumor passes out of the medullary cavity: the cells infiltrate along the nutrient artery and form a subperiosteal tumor; $\times 80$.

tumors in the chickens illustrated admirably two ways by which a medullary tumor reaches the subperiosteal region: one by way of the nutrient foramen, and another by growing between bone spicules and along the haversian systems (figs. 8 and 9).

So far as the second purpose is concerned, that is, the following of a tumor of bone from its inception to its termination, there may be

1. Connor, C. L.: Endothelial Myeloma, Ewing, Arch. Surg. **12**:789 (April) 1926.

2. Codman, E. A.: The Nomenclature Used by the Registry of Bone Sarcoma. Am. J. Roentgenol. **13**:105, 1925.

differences of opinion as to how far one may go in comparing a tumor in the chicken to one in man. Generally, in man, a tumor has been present for a considerable period before attention is called to it by some untoward occurrence, but usually there is no means of ascertaining how long. The factor of pain, of course, was not evident in the tumors in the chickens, if present. Most of the chicks showed no signs of distress until metastases were far advanced. Two only limped, and each of these had developed small nodules on the articular cartilage at the site of injection. Pain, as a rule, is the symptom that draws attention to a tumor of bone in man, although cases are not infrequent in which a spontaneous

Fig 9.—Another way in which a subperiosteal tumor is formed: the cells of an endothelioma infiltrate through bone trabeculae and pass along beneath the periosteum; $\times 80$.

fracture is the first sign. One cannot compare the two growths, therefore, in this respect. One may only record that, in the chickens, fully two thirds of the course of the tumors had been run before they were detectable, in spite of the fact that first signs were eagerly awaited.

There has been discussion regarding the nature and causes of the new formation of bone in both primary and metastatic tumors of bone. It is fairly well agreed that the formation of new bone around a metastatic carcinoma or a giant cell tumor is a reparative, reactive or defensive process, similar to the fibrosis occurring around tumors in soft tissues.

But it is conceded that osteogenic tumors form tumor bone, and many older pathologists professed to distinguish between bone formed by tumor cells and that formed by normal osteoblasts. Many osteogenic tumors form abortive or malformed bone, but many also form bone that is indistinguishable from that seen in a normal callus. Eising,³ on philosophical evidence, believed that the bone formed in all tumors is reactive, and not formed by tumor cells. It seems reasonable, however, that osteoblasts in an osteogenic tumor might form an osseous tissue just as fibroblasts in a fibrosarcoma may, and do, form collagen.

Fig. 10.—Formation of bone, apparently by tumor cells, between the periosteum and the cortex; $\times 80$.

Granting, then, that tumor cells may form bone, from what cell or cells may osteoblasts be derived? In most cases, these undoubtedly arise from spindle cells (fibroblasts?) of the periosteum and endosteum. The latter, however, is in man a rather indefinite membrane, and in young animals osteoblasts may apparently be derived from the marrow.⁴

Fig 11—Three stages of growths in chicks of the same age, all at twenty-one days

Moschcowitz,⁵ discussing heterotopic formation of bone, declared that the osteoblast comes from an endothelial cell lining blood vessels, and further stated that a common cell (fibroblast?) forms the endothelial cell, the osteoblast and the bone-marrow cell. Maximow⁶ derived the histiocyte, the fibroblast and the reticular cell from a common mesenchymal cell, and the osteoblast from the fibroblast. Fibrils, similar to those of a fibroblast, may be formed by the monocyte in tissue cultures.⁷

In the present experiments, two types of tumors, a fibrosarcoma (Rous) and an endothelioma (or reticuloma), produced bone under one condition only, namely, when the cells were confined between the periosteum and the cortex. There are probably three reasons for this: (1) both types of cells are capable under certain conditions of forming osteoblasts; (2) the conditions are probably a suitable physicochemical milieu, such as is found in the region of bone, and (3) a mechanical restraint similar to that caused by tumor growing between a tautly drawn periosteum and the cortex of bone. Once the periosteum has been broken through, the tumors grow much more rapidly, and no intercellular substance of any kind is produced by the endothelioma.

SUMMARY

A spontaneous transmissible endothelioma of the chicken was introduced into the marrow cavity of the tibia of the chicken for the purpose of duplicating, if possible, a tumor similar to that described by Ewing as an endothelial myeloma, and in order to watch the development and manner of growth of such a tumor. The resultant tumor resembled, in some respects, both endothelioma and osteogenic sarcoma as seen in man. Like endothelioma, it occupied a large part of the shaft and was osteolytic until it had penetrated via the nutrient foramen or through the cortical spicules to the subperiosteal space. While confined between the periosteum and the cortex, the tumor cells formed radiating spicules of bone. In a similar experiment with the Rous fibrosarcoma, it, too, formed bone beneath the periosteum.

Fully two thirds of the course of the tumor had been run before the tumor became palpable or visible by the x-rays, although it was

present in all the bones examined on the fourth day. By the twenty-second day, the chickens had died with widespread metastases. Two died of metastases before a tumor could be demonstrated by palpation or by the x-rays, although tumors were present in both cases.

It is shown that both endothelial (or reticular) cells and fibroblasts are capable of differentiating into osteoblasts under certain physical and chemical conditions.

PULMONARY ATELECTASIS AND RESPIRATORY FAILURE *

ISRAEL RAPPAPORT

NEW YORK

In an earlier publication, I ¹ described the abrupt onset of respiratory embarrassment in cases of caseous pneumonic phthisis complicated by sudden atelectasis. Observation of a large number of severe and extensive cases of acute phthisis has convinced me that this complication is not the exception, but rather the rule, in such severe processes of the lungs. To illustrate the extent to which such conditions may progress, a case is here presented which is only one of many such observations. This particular case was chosen because it shows atelectasis of an entire lung which cleared up ultimately, in spite of catastrophic progress of the process itself. Furthermore, since this patient died of a miliary dissemination shortly afterward, an opportunity was afforded to check up on the pathologic changes.

The patient, J. G., aged 25, a bank clerk, became ill suddenly about six weeks previous to his admission, in the first days of January, 1925. His first roentgen examination is not reproduced here, as it was not much different from the plate given here with the date of March 4, 1925. The patient was too ill for any active therapy to be attempted. On April 9, 1925, he developed symptoms of acute respiratory distress. The plate of that date (fig. 2) reveals as the reason for the attack a massive atelectasis of the entire left side of the lung. Figure 3, taken on May 15, 1925, shows reinflation of the formerly collapsed lung, except for some extension of the process into the lower lobe, as compared with the first plate. The patient died two months later. Autopsy revealed vast honeycombing throughout the left lung, with cavities of different sizes and shapes. The intervening pulmonary tissue was studded with tubercles. The pleura of the left side was densely adherent. The right lung showed lobular involvement in the upper lobe and miliary dissemination throughout the rest of the lung.

Here, then, was a case in which spread of an acute exudative process from the upper to the lower lobe was accompanied by a temporary collapse of the entire lung. Atelectasis and retraction of severely affected lungs in the course of phthisis has been described in the literature repeatedly; recently Packard ² reported such cases. More or less atelectatic collapse of severe tuberculous lesions has been observed to be a regular feature of phthisis. That atelectasis is also a regular

* Submitted for publication, April 29, 1929.

2. Packard, E. H.: *Am. Rev. Tuberc.* 18:7, 1928.

feature of other severe pulmonary diseases has become increasingly evident within the last decade. Churchill and Holmes³ reported atelectasis in pulmonary suppuration of pyogenic etiology. The Philadelphia workers on atelectasis conclusively demonstrated its presence in all post-operative complications of the lungs. Coryllos and Birnbaum⁴ recently presented experimental evidences to prove that atelectasis is the underlying pathologic change of all pneumonic processes.

In short, there is ample clinical and pathologic evidence to the fact that pulmonary processes of whatever etiology are accompanied by atelectasis of greater or lesser areas of the lungs. The clinical symptoms

Fig. 1.—Lungs of the patient, J. G., taken on March 4, 1925

of atelectasis are identical, regardless of the underlying pulmonary disease. The symptoms of critical pneumonia, massive collapse or any other critical condition of the lungs are exactly the same; they are those I have described under the name of "anoxemic cardiac syndrome." They are the symptoms of acute respiratory embarrassment, which vary in intensity according to the proportion of breathing surface failing

in function, and according to the compensatory capacity of the breathing surface remaining in function. In the aforementioned paper on the respiratory failure syndrome, I have described its acute form and emphasized that it shows a wide range of variations according to the degree of respiratory dysfunction present. As a basis for the discussion in that paper, I adopted the present day pathologic concept that respiratory embarrassment leads to failure by way of cardiac exhaustion and that the clinical phenomena are therefore cardiac in origin. However, even at the time that the paper was published I believed in a different conception of respiratory failure, but I was not yet ready to bring out the subject in the light of my own conceptions.
